Appendix I, CASA models

Jui-Han Chang and Deborah R Hart
Northeast Fisheries Science Center

Introduction

This Appendix describes the changes to the CASA model from that used in the 2018 benchmark (NEFSC 2018), and gives detailed CASA model results. For more details regarding the CASA model, see Hart et al. (2013) and NEFSC (2018), and in particular, its Appendix 6. Unless otherwise specified, the CASA models were configured as in the 2018 benchmark. There are three separate CASA models for the Mid-Atlantic, Georges Bank Open and Georges Bank Closed areas. These were separated to account for different life history parameters (especially between the Mid-Atlantic and Georges Bank), and different fishing mortality patterns (in particular between Georges Bank Closed and Open). The results of these models are combined to obtain estimates for the whole stock.

As in the 2018 benchmark, the scallops in the deep water (> 70 m) southeast portion of the Nantucket Lightship area were not included in any of the models. This is because these scallops are growing anomalously slowly and were not fished prior to 2020, and because there is no history of scallops in this area prior to settlement of the large 2012 year class. Biomass in this area is determined empirically, using the Habcam survey. We discuss each of the three CASA models in turn.

Model Configuration

CASA Model for Georges Bank Closed Areas

The model was tuned to the lined dredge survey (1979-2019), the SMAST large video drop camera survey (2003-2012, and 2014), the SMAST digital drop camera survey (2015 and 2017), the Habcam survey (2011-2019), and the unlined dredge survey (1975 and 1977). Neither the Habcam nor the SMAST survey covered all of this area in 2019, but they can be combined to obtain a complete survey; for time series purposes, this combined survey was considered to be part of the Habcam survey. Four fishery selectivity periods were used. The first two were as in the 2018 benchmark, with the first comprising the years prior to the fishery closures (1975-1994), and the second the period after the reopenings until 2017 (1998-2017). Selectivity changed in 2018 and 2019 due to the reopening of the Nantucket Lightship West area, which had less very large scallops than is typical in the closed areas. Selectivity was modeled separately for each of these two years. The 2019 period was modeled as domed (double logistic) selectivity, due to heavy fishing in the Nantucket Lightship West Area that targeted intermediate sized scallops. All the other periods were assumed to have logistic selectivity.

The four growth matrices used in the 2018 benchmark were also used for the 2020 model: matrix 1 for 1993-1996 and 2011-2019, matrix 2 for 2000-2006, matrix 3 for 1975-1992 and 1997-1999, and matrix 4 for 2007-2010. The growth matrices were based on a mixed-effects model that estimates von Bertalanffy parameters and their variation based on shell ring increments (Hart and Chute 2009). Based on survey size-frequencies, growth in recent years has been relatively slow, likely due to the slow growing large 2012 year class. For that reason, the matrix representing the slowest growth (matrix 1), was used to model growth from 2011-2019.

CASA Model for Georges Bank Open Areas

The model was tuned to the lined dredge survey (1979-2019), the SMAST large drop video camera survey (2003-2012, and 2014), the digital drop camera survey (2015, 2017, and 2019), the Habcam survey (2011-

2018), and the unlined dredge survey (1975 and 1977). As in the Georges Closed Area, neither the drop camera and Habcam surveys covered all portions of the Georges Bank Open areas in 2019, so these were combined to obtain a survey that covered all areas. For time series purposes, these data were considered to be a part of the digital drop camera survey.

As in the 2018 benchmark, there were three commercial fishery selectivity periods: 1975-1998, 1999-2004, and 2005-2019. Five discontinuous growth periods were used for Georges Bank open stock (period 1 from 1993-1996; period 2 from 2000-2006 period 3 from 1975-1992 and 1997-1999; period 4 from 2007-2011; and period 5 from 2012-2019). The growth matrices used for period 1-4 were as in the 2018 benchmark, whereas the matrix for period 5 were based on shell increment data from those years, much of it new.

CASA Model for Mid-Atlantic Areas

The Mid-Atlantic CASA model uses all the surveys employed in the Georges Bank models plus the NEFSC winter bottom trawl survey, which was conducted between 1992-2007. The fishery selectivity periods were the same as the 2018 benchmark (with two years added to the last period): 1975-1979, 1980-1997, 1998-2001, 2002-2004 and 2005-2019. The first period was modeled as domed (double logistic) selectivity, due to indications in the data of higher mortality on intermediate sized scallops. All the other periods were assumed to have logistic selectivity.

As in the 2018 benchmark, three discontinuous growth periods were used for the Mid-Atlantic region: 1975-1977, 1987-2003, and 2006 (matrix 1, slow growth), 1978, 1983-1986, 2004-2005, and 2007 (matrix 2, moderate growth), and 1979-1982 and 2008-2011 (matrix 3, fast growth). Growth matrix 1 were used for 2012-2019 based on the observed slow growth from surveys in those years.

Model Results

The models generally had good fit to the data, with only moderate retrospective patterns; Mohn's ρ ranged from 0.23 to 0.33 for biomass and from -0.03 to 0.41 for fishing mortality. Much of these retrospective patterns were due to anomalous natural mortalities associated with large year classes. Although the CASA models can estimate temporal variations in natural mortality, large mortality events that occur near the terminal year cannot be precisely estimated due to the lack of data. As more years of data are added, the M estimates become more stable and precise. In particular, there was a large decline in biomass and abundance in the Nantucket Lightship West area between $2018 - 2019$ beyond what could be accounted for by landings and mean natural mortality. With only a single year's data after the decline, the CASA model has insufficient information to estimate a large increase in M for those years. Additionally, the uncertainties surrounding estimated growth for recent years may be causing uncertainty in estimated biomass.

We present updates of all the CASA model tables and figures from the 2018 benchmark.

Figures

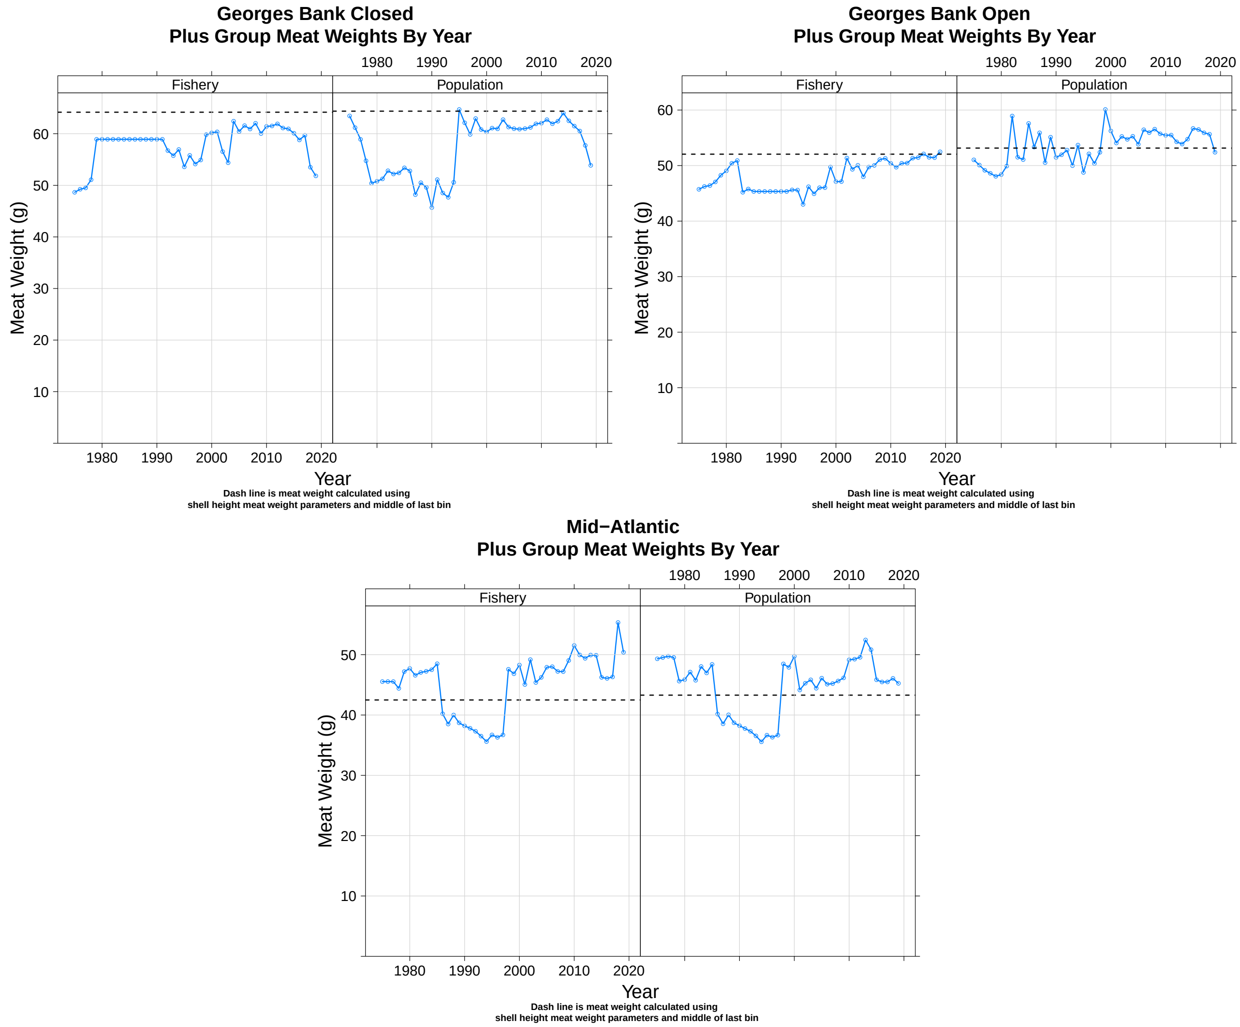

Figure 1: Estimated plus group meat weights for the population and fishery in the open and closed portions of Georges Bank, and in the Mid-Atlantic. The plus group represents scallops in the largest bin which contained L_∞. The dashed line is the meat weight for the last size bin calculated using the shell height meat weight parameters used in the CASA model.

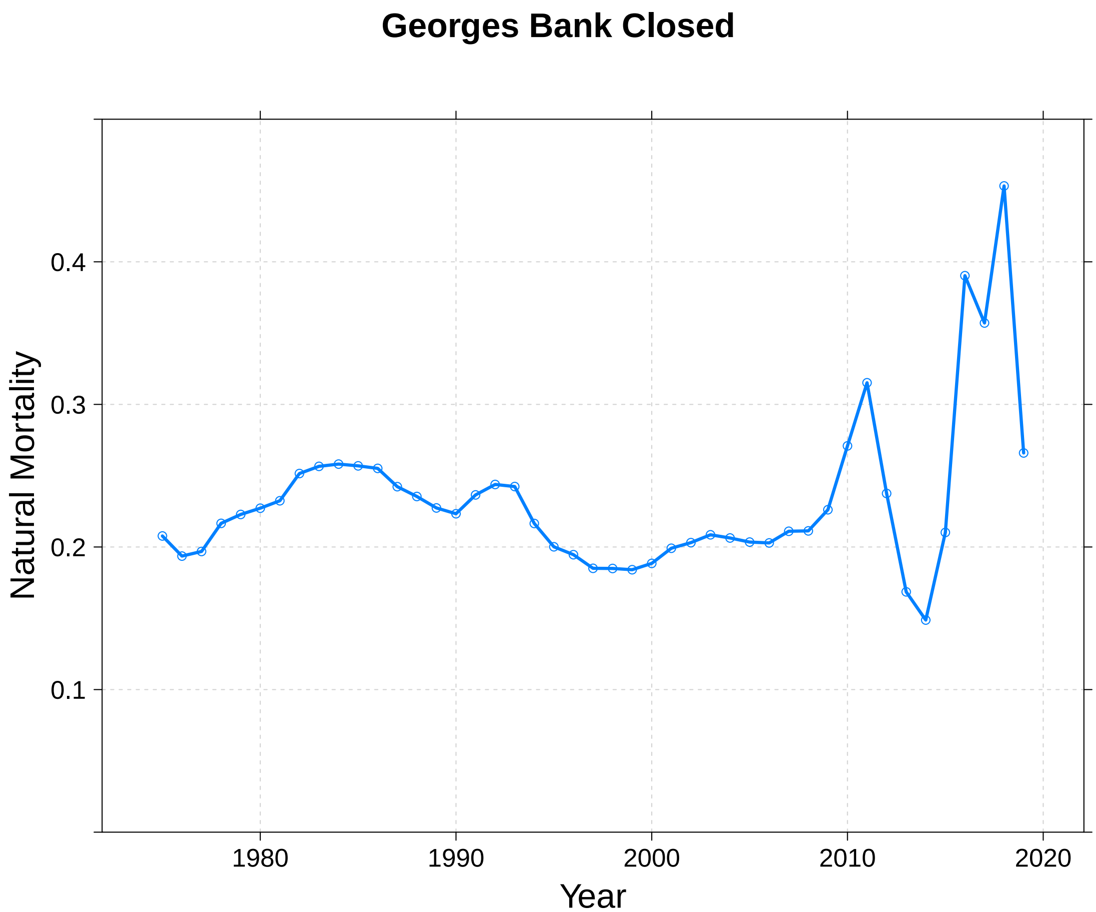

Figure 2: Estimated natural mortality from 1975 to 2019 for the Georges Bank closed areas.

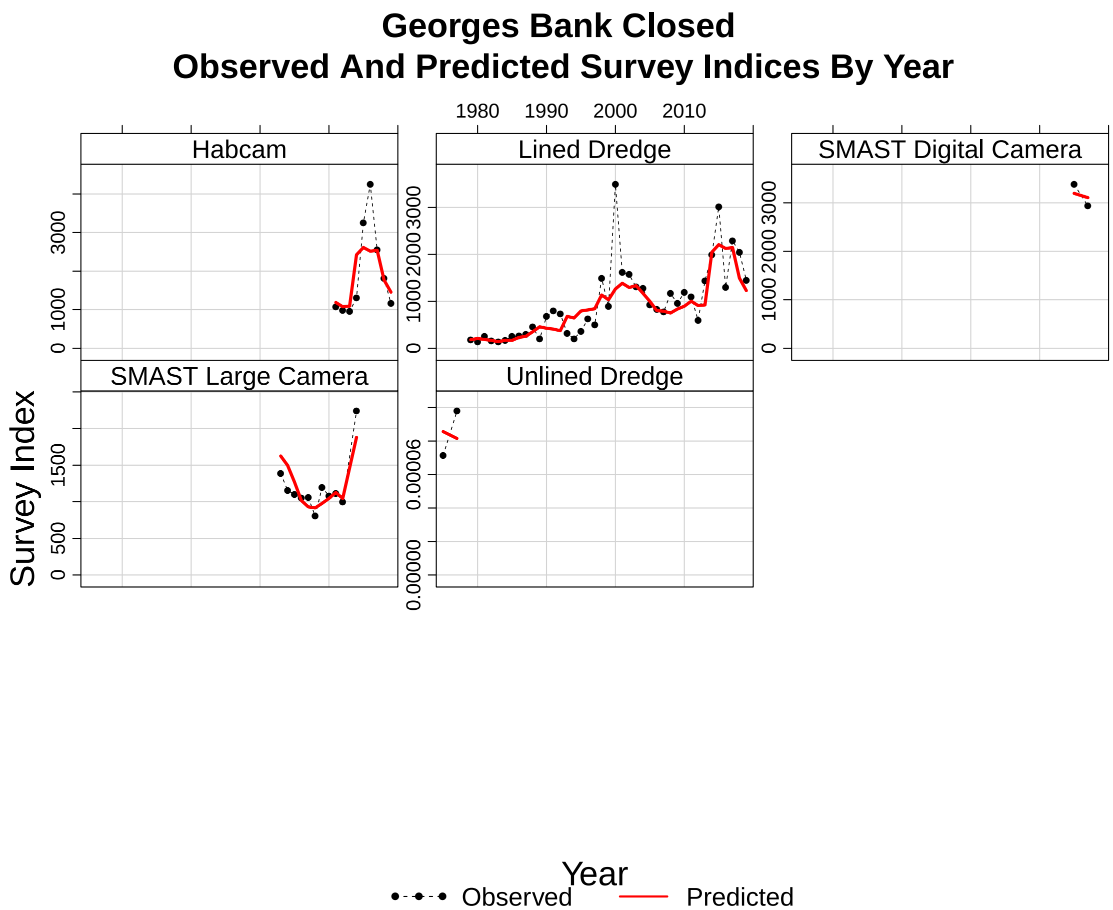

Figure 3: Observed survey trend (solid circles) and corresponding model estimates (lines) for the SMAST digital camera (top left), lined dredge (top middle), Habcam (top right), SMAST large camera (bottom left), and unlined dredge (bottom middle) surveys on Georges Bank closed areas.

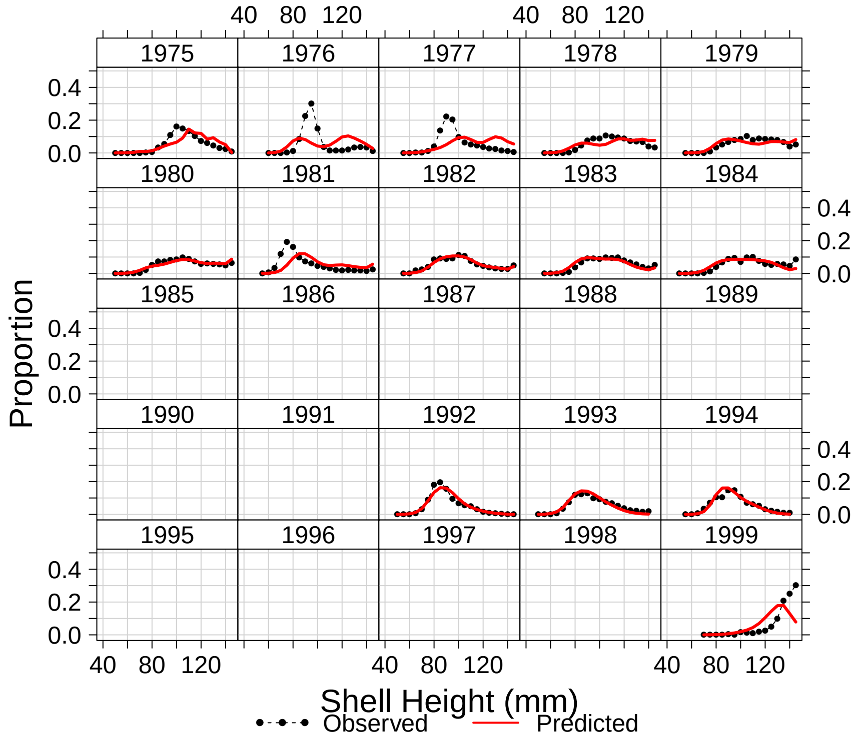

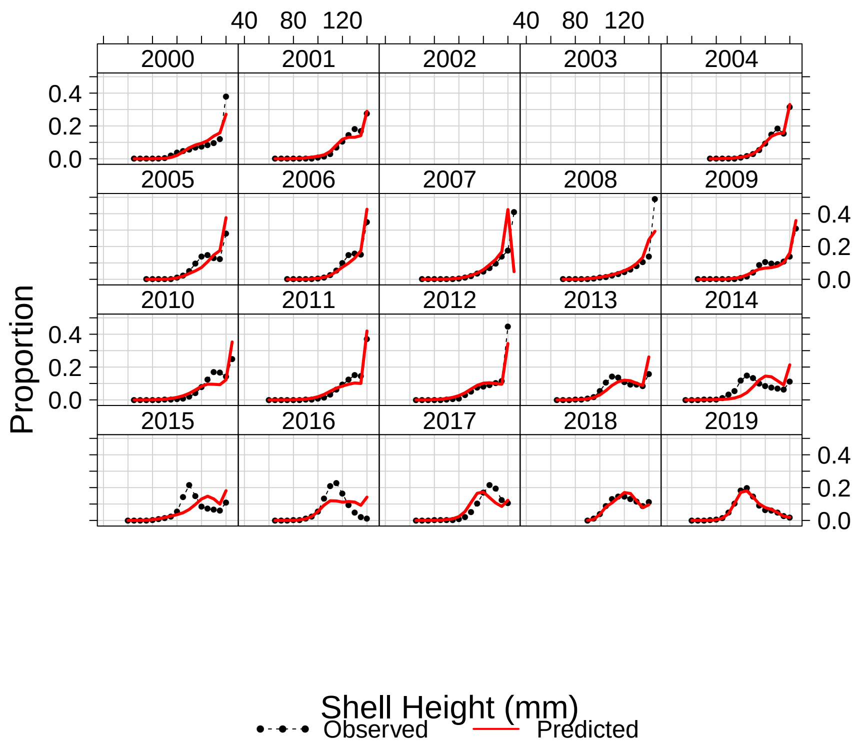

Figure 4: Comparison of observed fishery shell height proportions (solid circles) and model estimated fishery shell height proportions (lines) for Georges Bank closed areas.

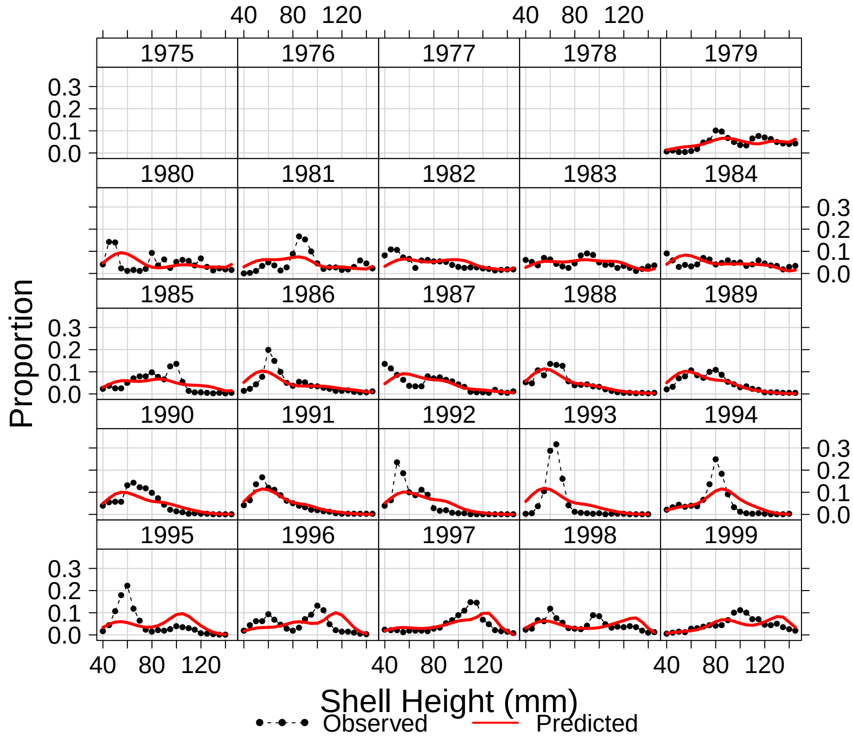

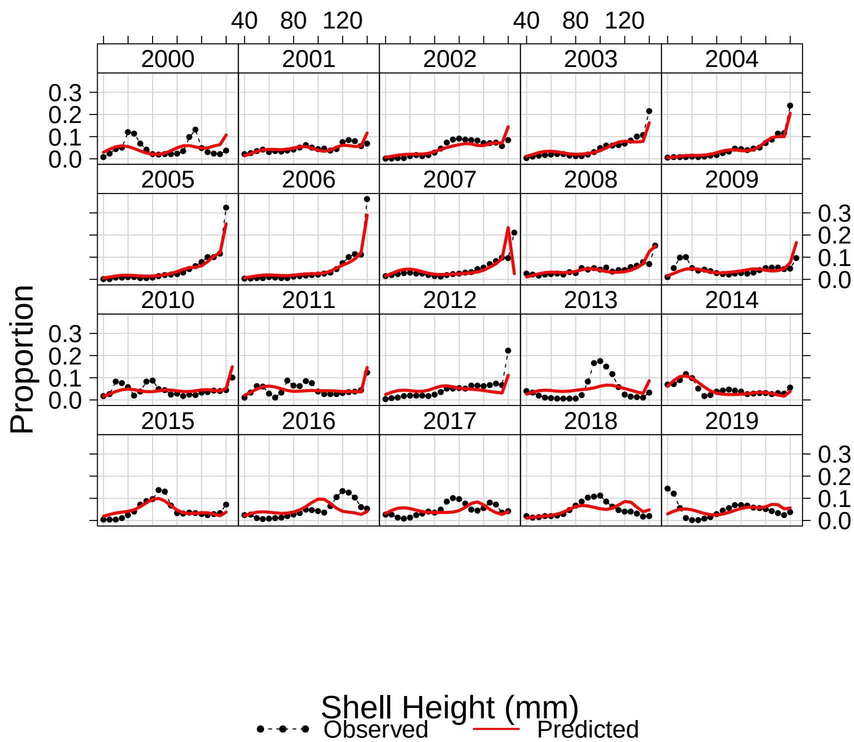

Figure 5: Comparison of lined dredge survey shell height proportions (solid circles) and model estimated shell height proportions (lines) for Georges Bank closed areas.

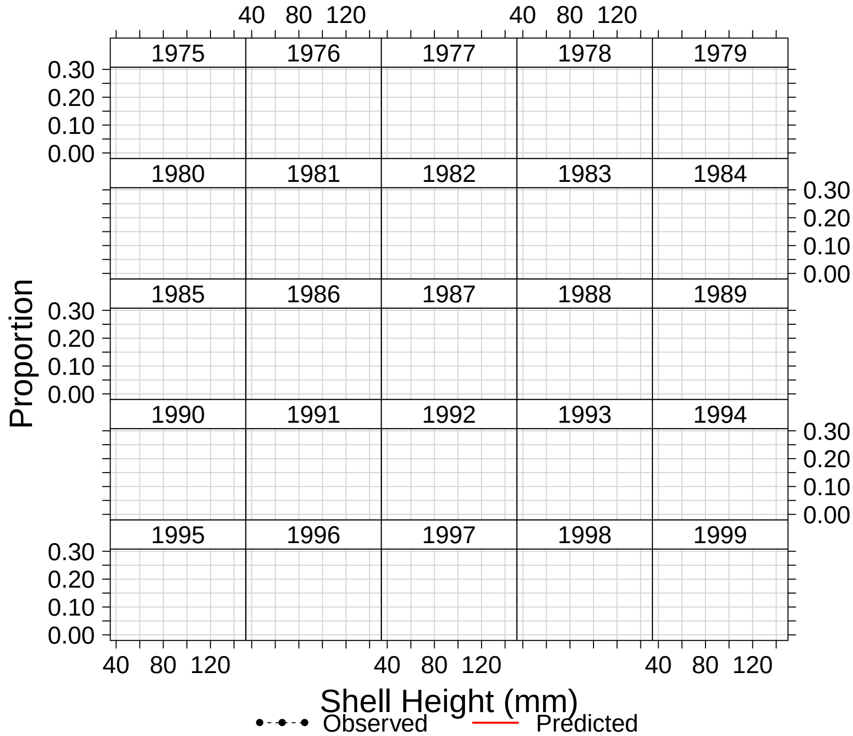

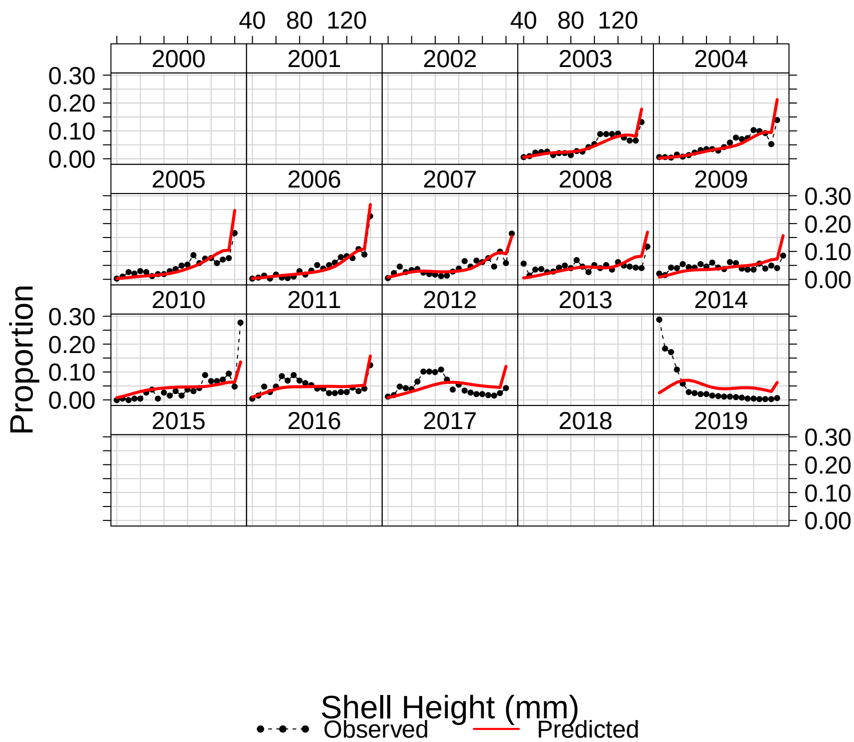

Figure 6: Comparison of SMAST large camera survey shell height proportions (solid circles) and model estimated shell height proportions (lines) for Georges Bank closed areas.

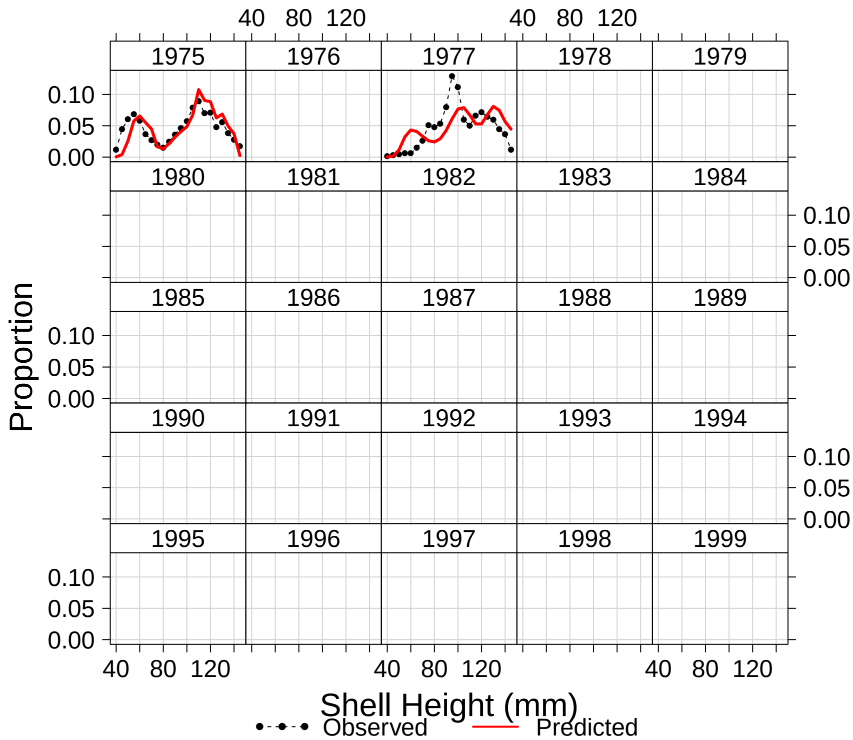

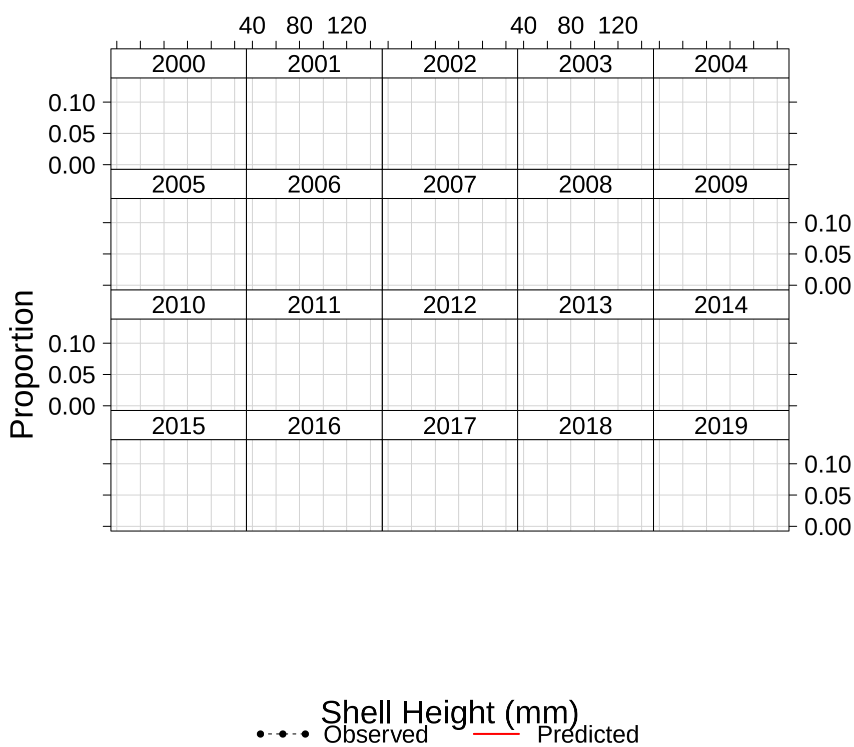

Figure 7: Comparison of unlined dredge survey shell height proportions (solid circles) and model estimated shell height proportions (lines) for Georges Bank closed areas.

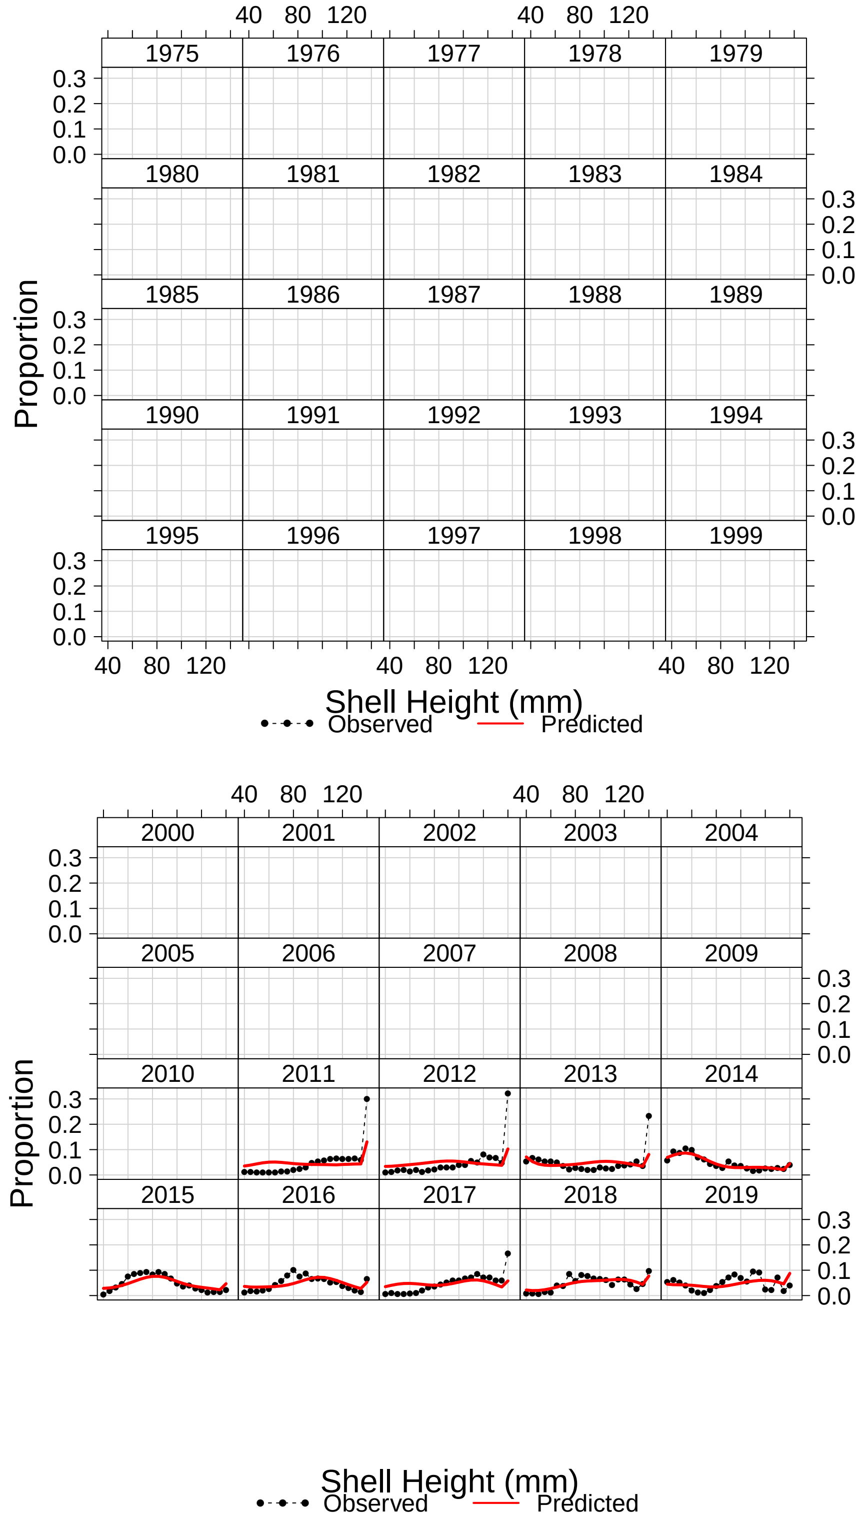

Figure 8: Comparison of Habcam survey shell height proportions (solid circles) and model estimated shell height proportions (lines) for Georges Bank closed areas.

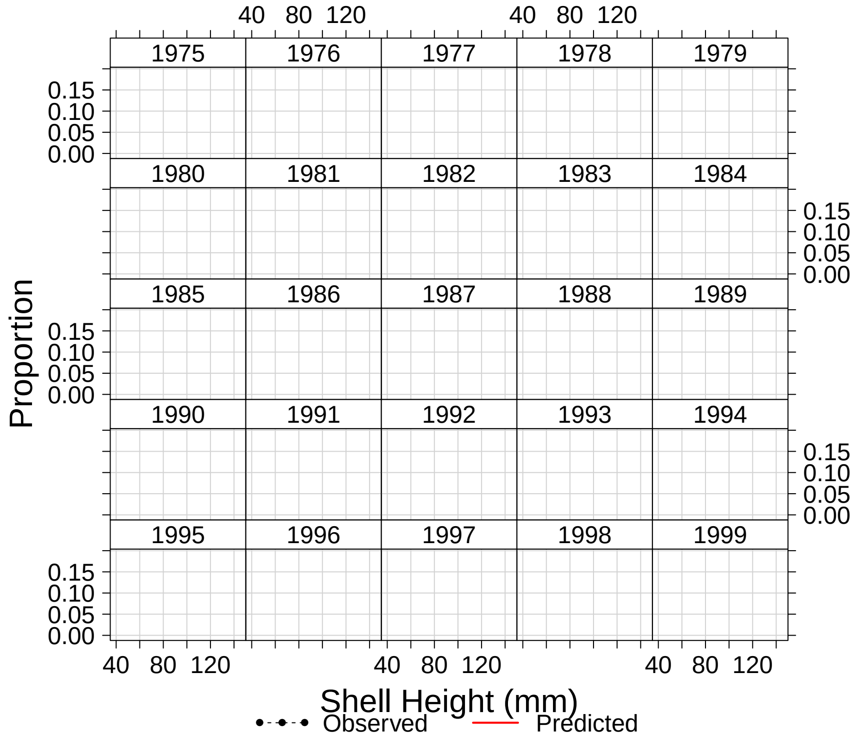

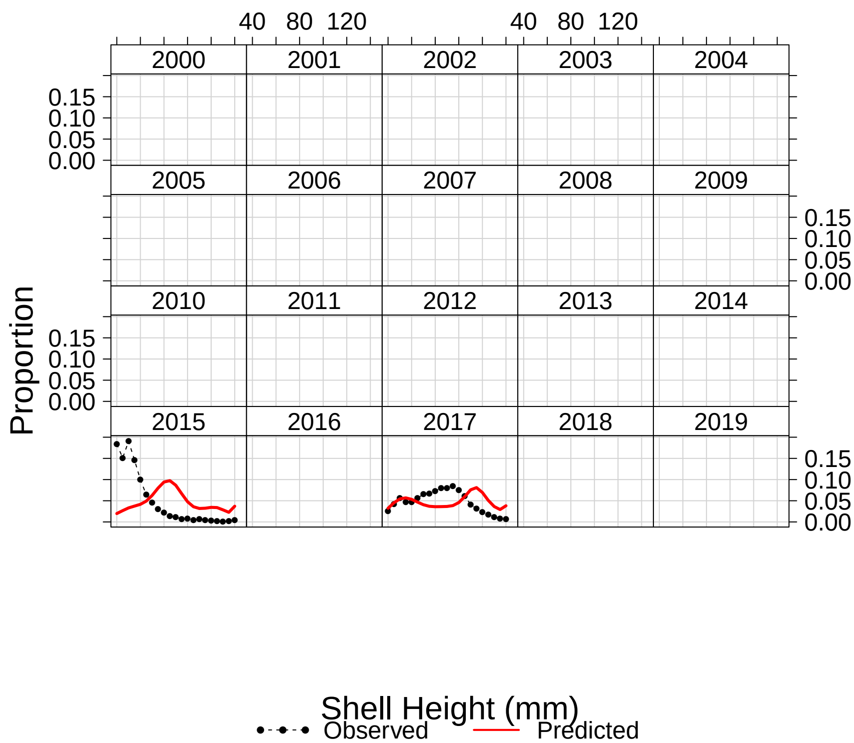

Figure 9: Comparison of SMAST digital camera survey shell height proportions (solid circles) and model estimated shell height proportions (lines) for Georges Bank closed areas.

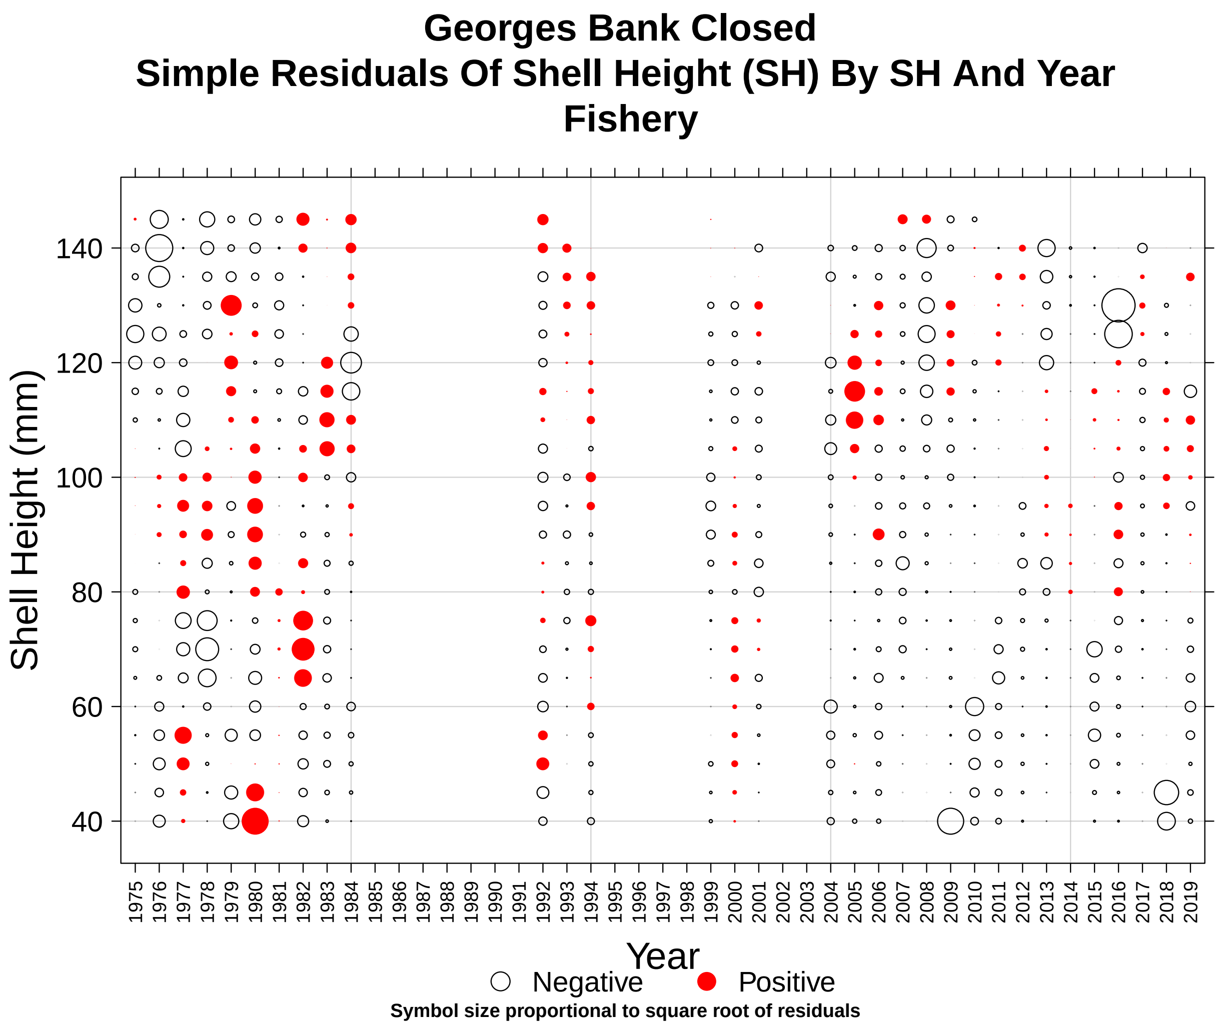

Figure 10: Simple residuals of fishery shell height proportions for Georges Bank closed areas. Symbol areas are proportional to residual.

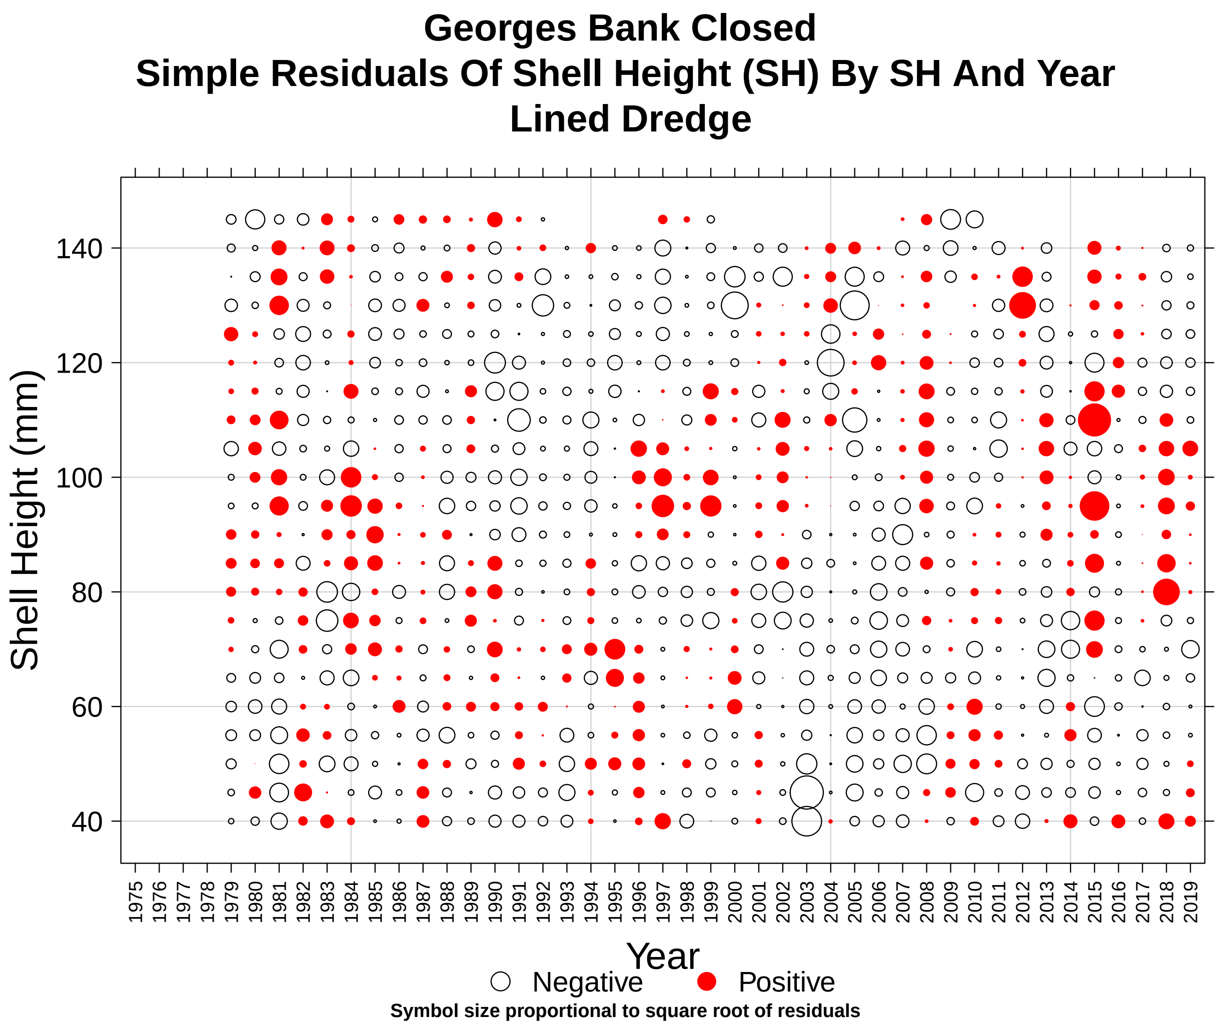

Figure 11: Simple residuals of lined dredge survey shell height proportions for Georges Bank closed areas. Symbol areas are proportional to residual.

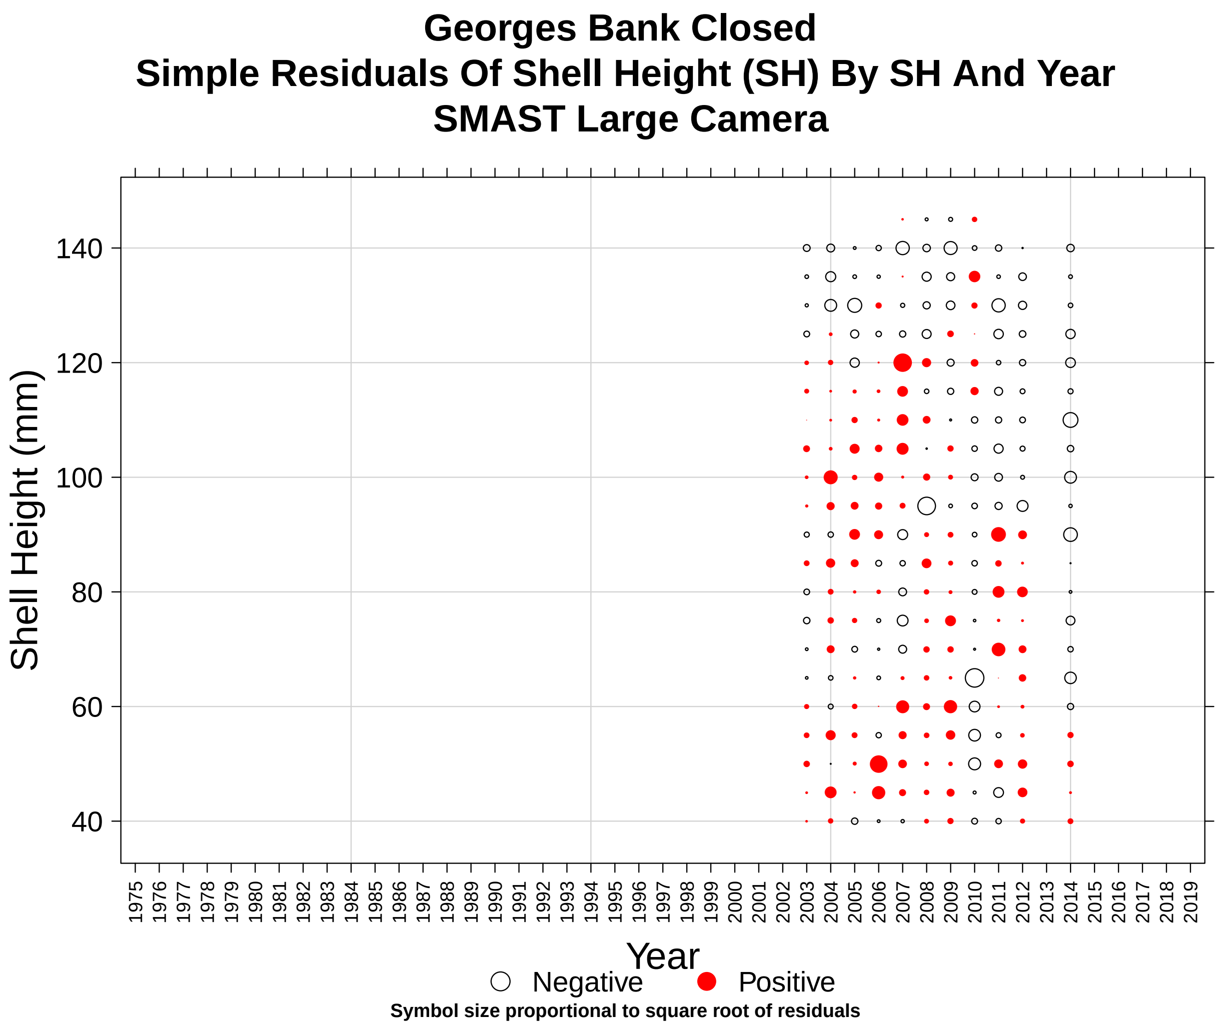

Figure 12: Simple residuals of SMAST large camera survey shell height proportions for Georges Bank closed areas. Symbol areas are proportional to residual.

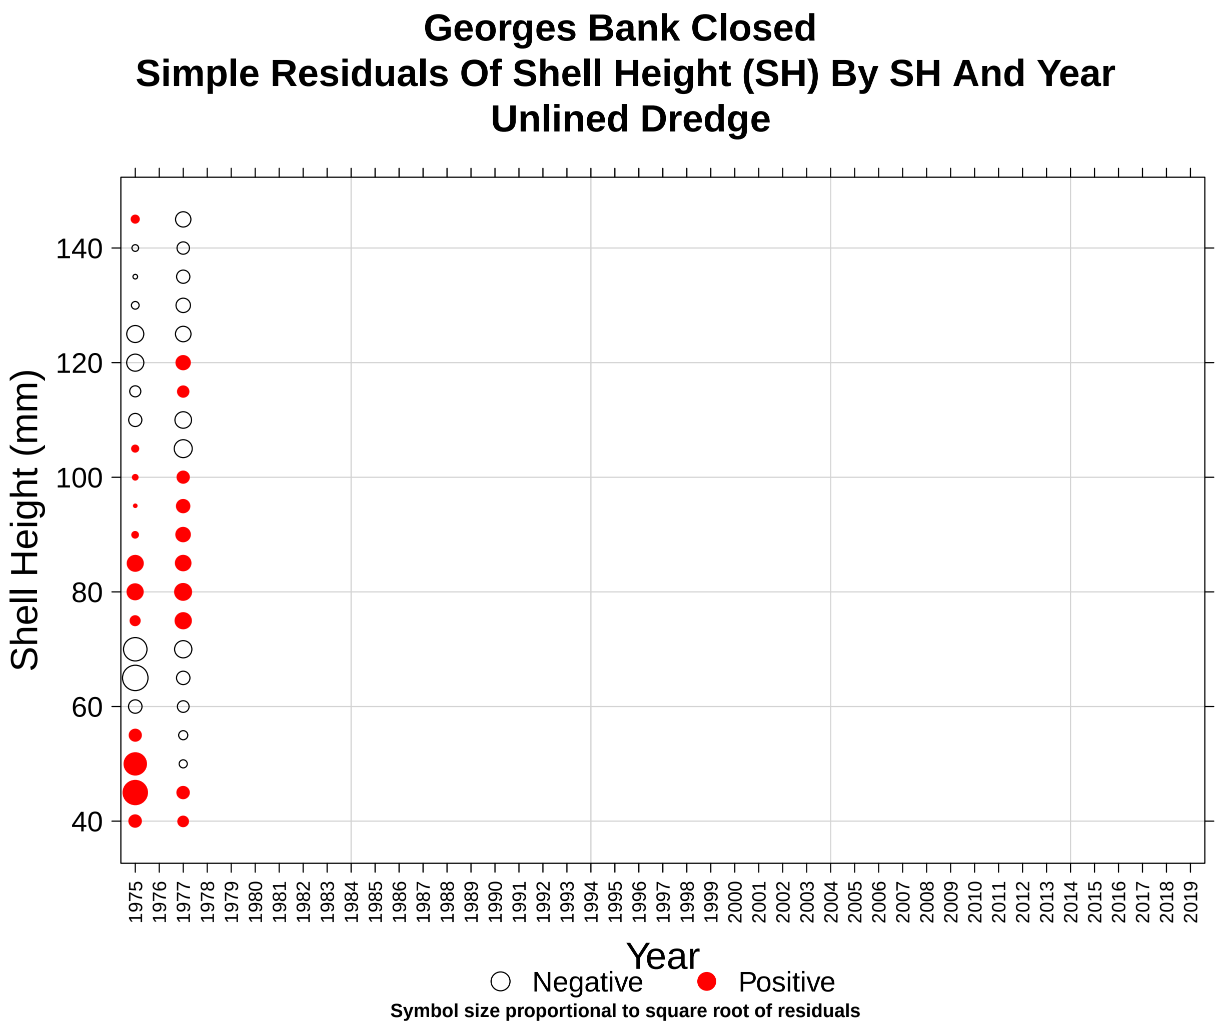

Figure 13: Simple residuals of unlined dredge survey shell height proportions for Georges Bank closed areas. Symbol areas are proportional to residual.

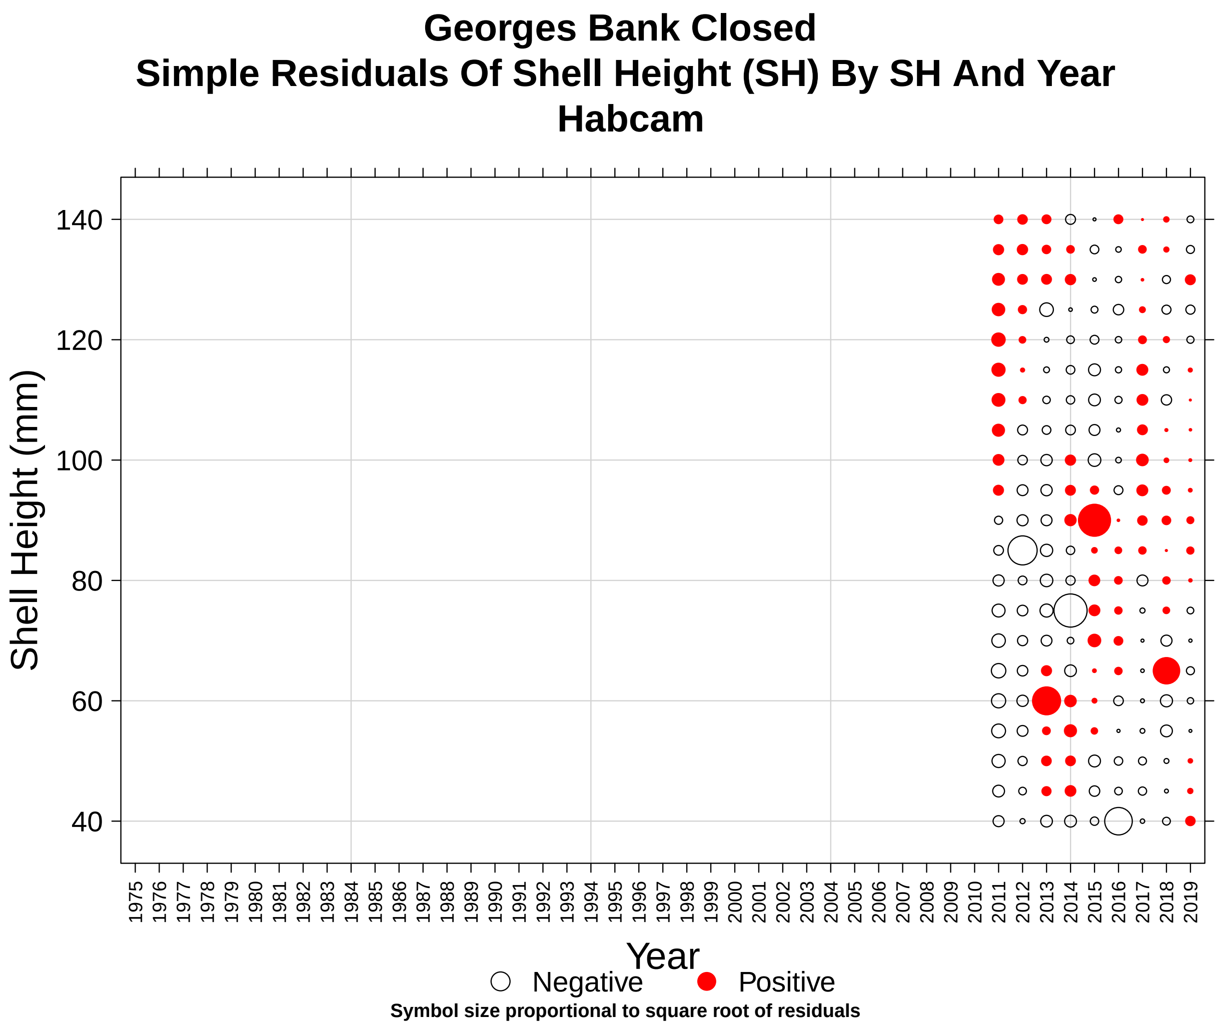

Figure 14: Simple residuals of Habcam survey shell height proportions for Georges Bank closed areas. Symbol areas are proportional to residual.

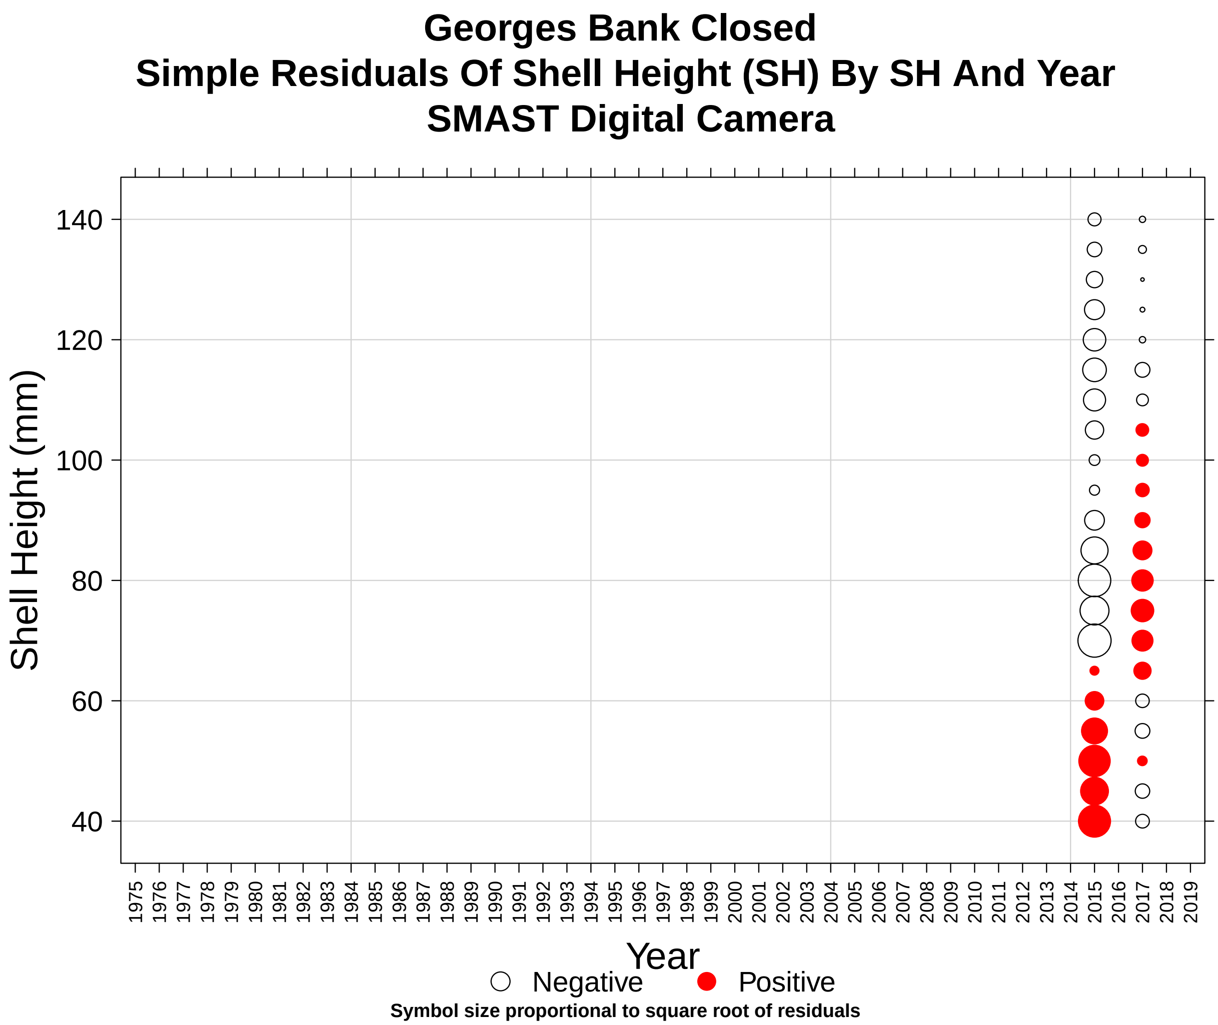

Figure 15: Simple residuals of SMAST digital camera survey shell height proportions for Georges Bank closed areas. Symbol areas are proportional to residual.

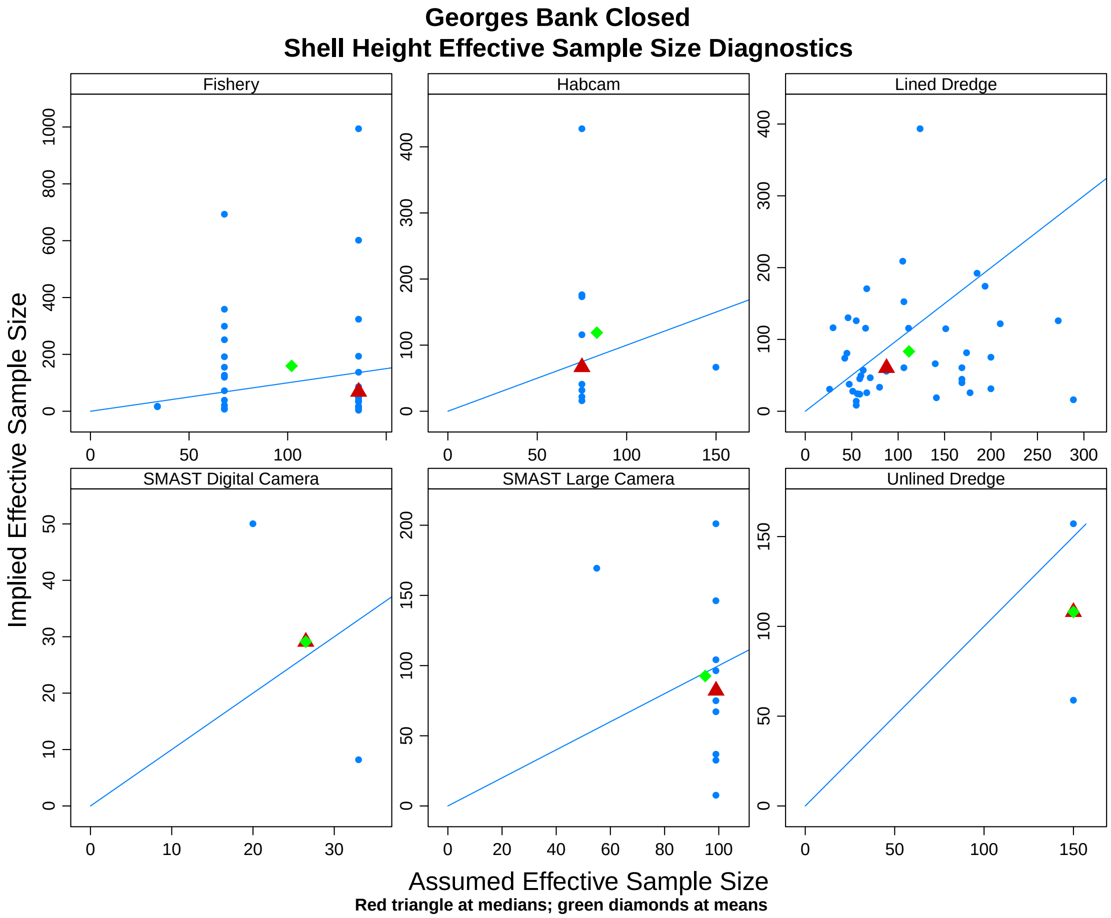

Figure 16: Assumed and model implied effective sample sizes for SMAST digital camera, lined dredge, Habcam, SMAST large camera, and unlined dredge surveys, and the fishery shell height compositions for Georges Bank closed areas. The triangle is the median and the diamond is the mean.

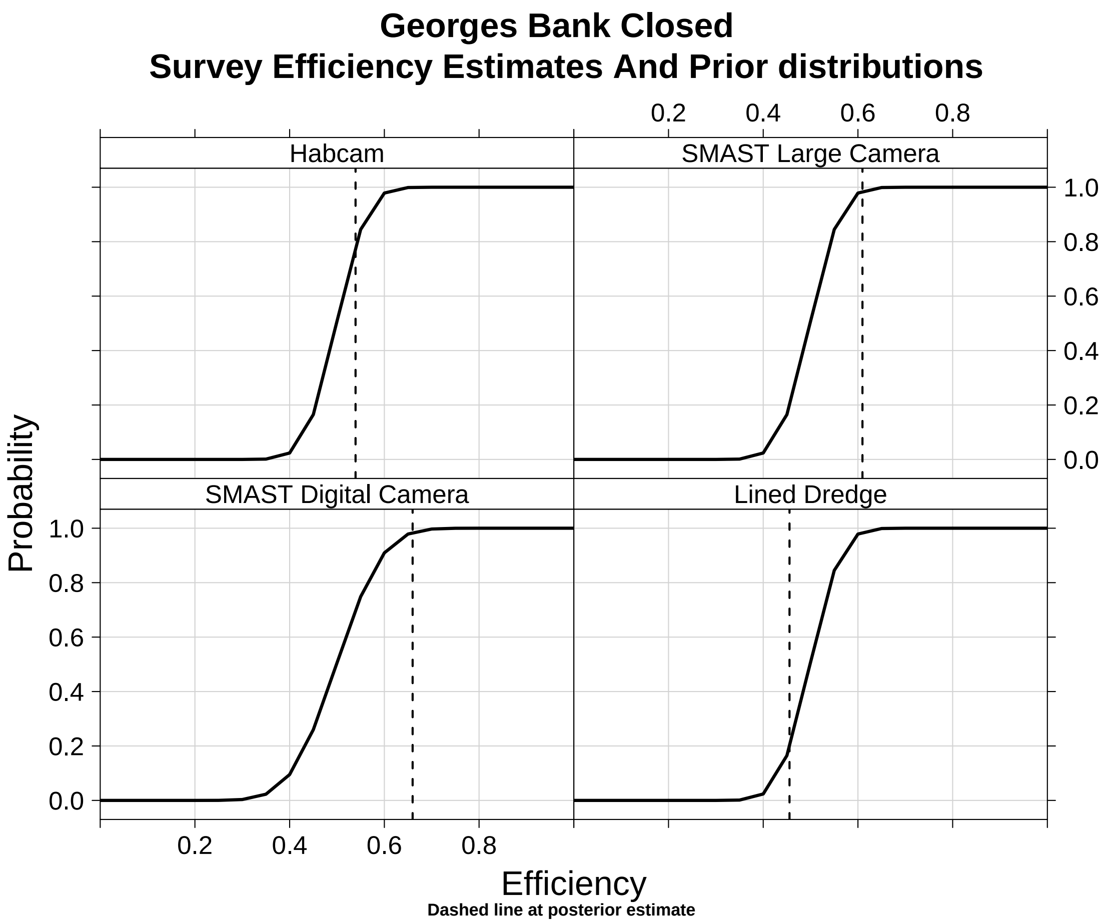

Figure 17: Prior cumulative distributions for catchability of Habcam, SMAST large camera, SMAST digital camera, and lined dredge surveys for Georges Bank closed areas. The dashed lines are the mean posterior estimate for survey catchability. For the purposes of this plot, the surveys were adjusted to have a mean prior catchability of 0.5.

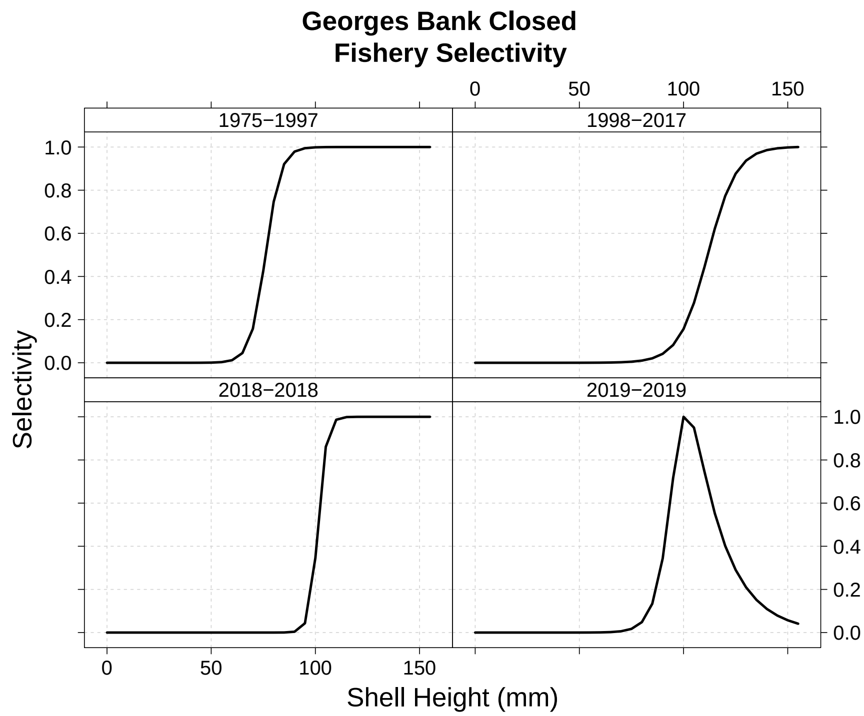

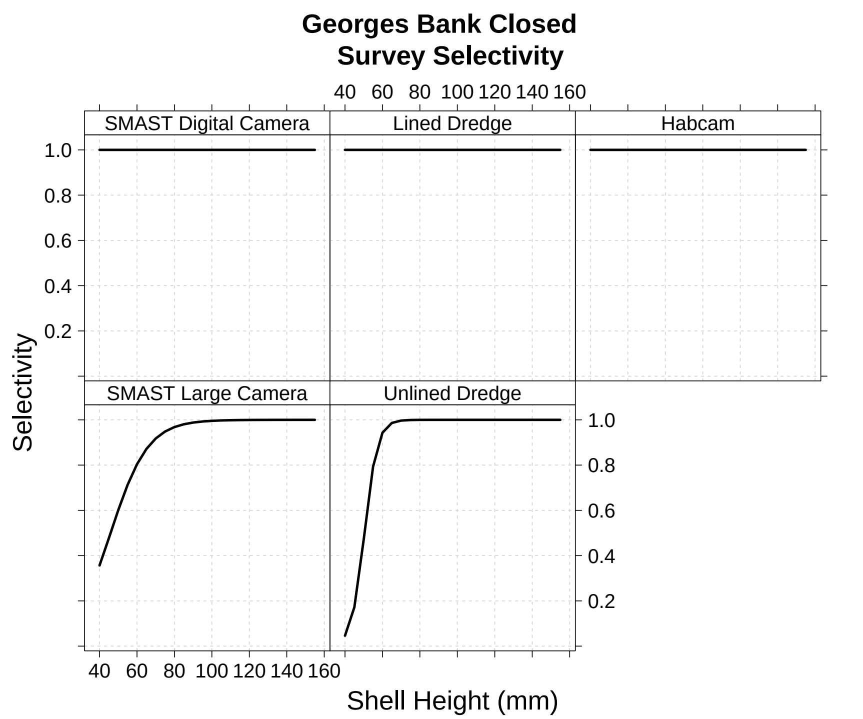

Figure 18: Estimated fishery selectivity curves (top) and assumed selectivity curves (bottom) for SMAST digital camera, lined dredge, Habcam, SMAST large camera, and unlined dredge surveys for Georges Bank closed areas.

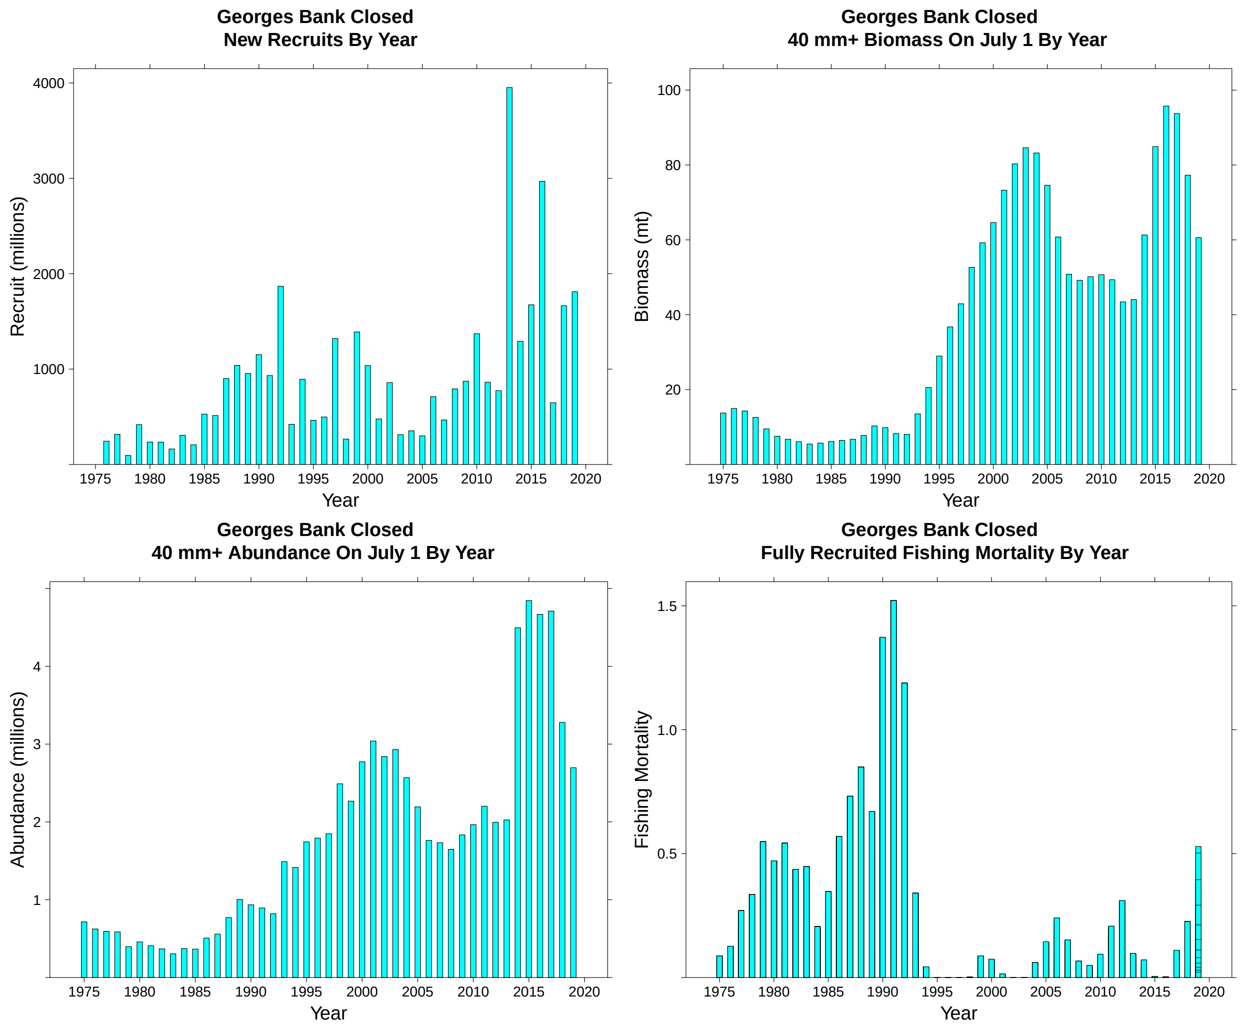

Figure 19: CASA model estimated recruitment (top left), July 1 biomass (top right), July 1 abundance (bottom left) and fully recruited fishing mortality (bottom right) for Georges Bank closed areas.

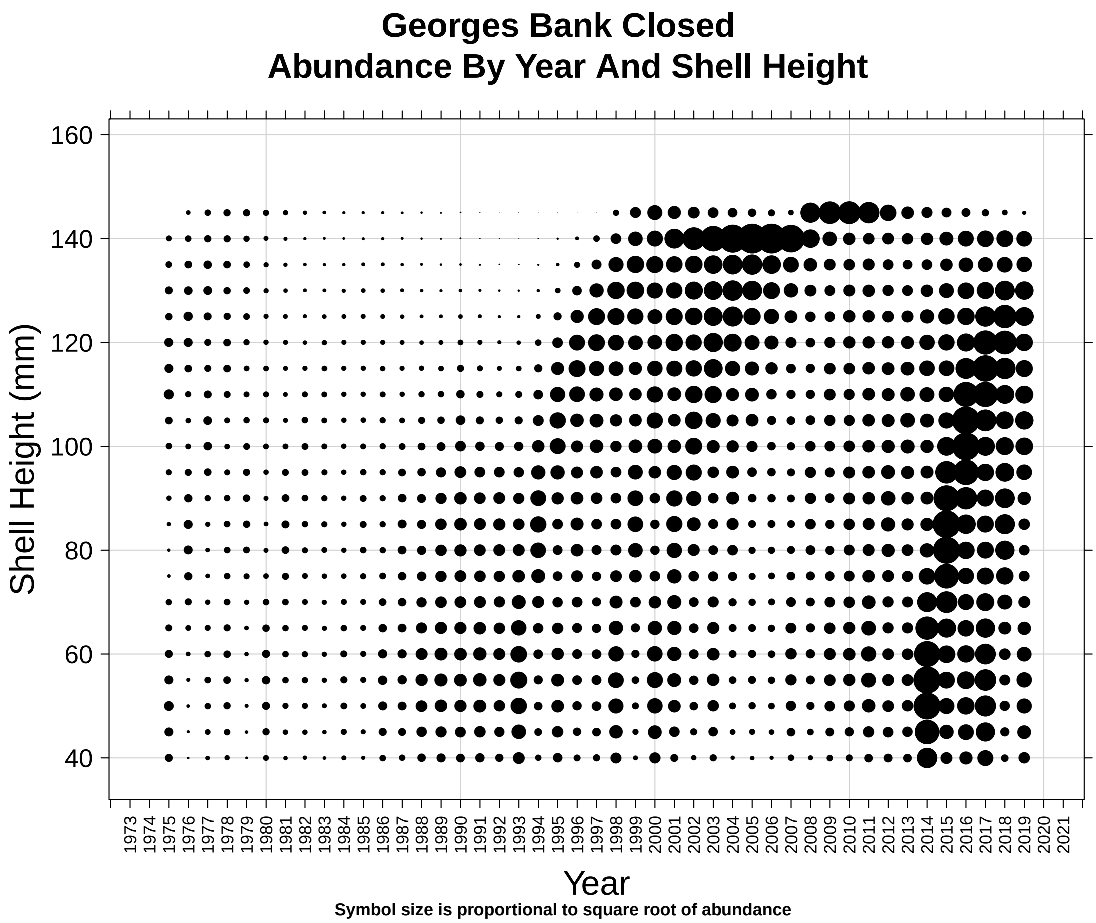

Figure 20: CASA model estimated abundances at shell height for Georges Bank closed areas. Symbol areas are proportional to abundance.

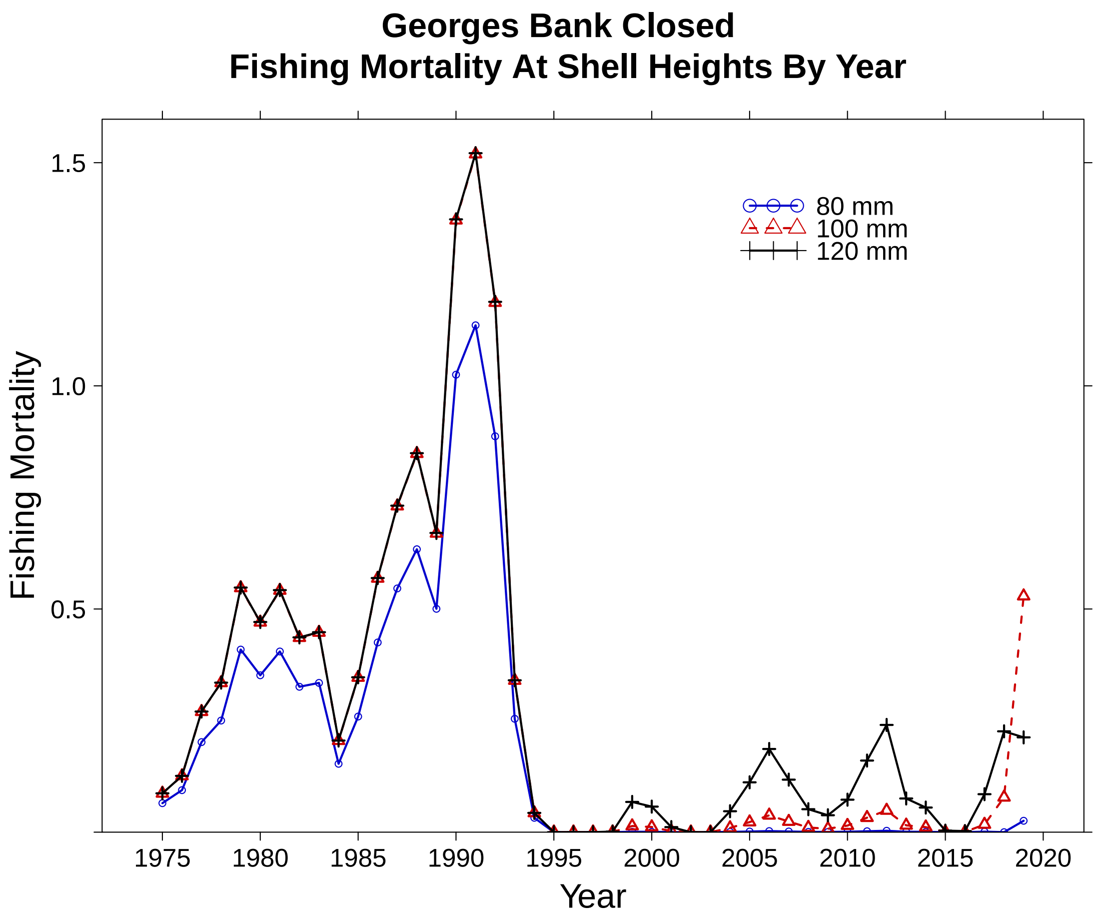

Figure 21: CASA model estimated fishing mortality at 80 mm (solid line with circles), 100 mm (dashed line with triangles), and 120 mm SH (dashed line with crosses) for Georges Bank closed areas.

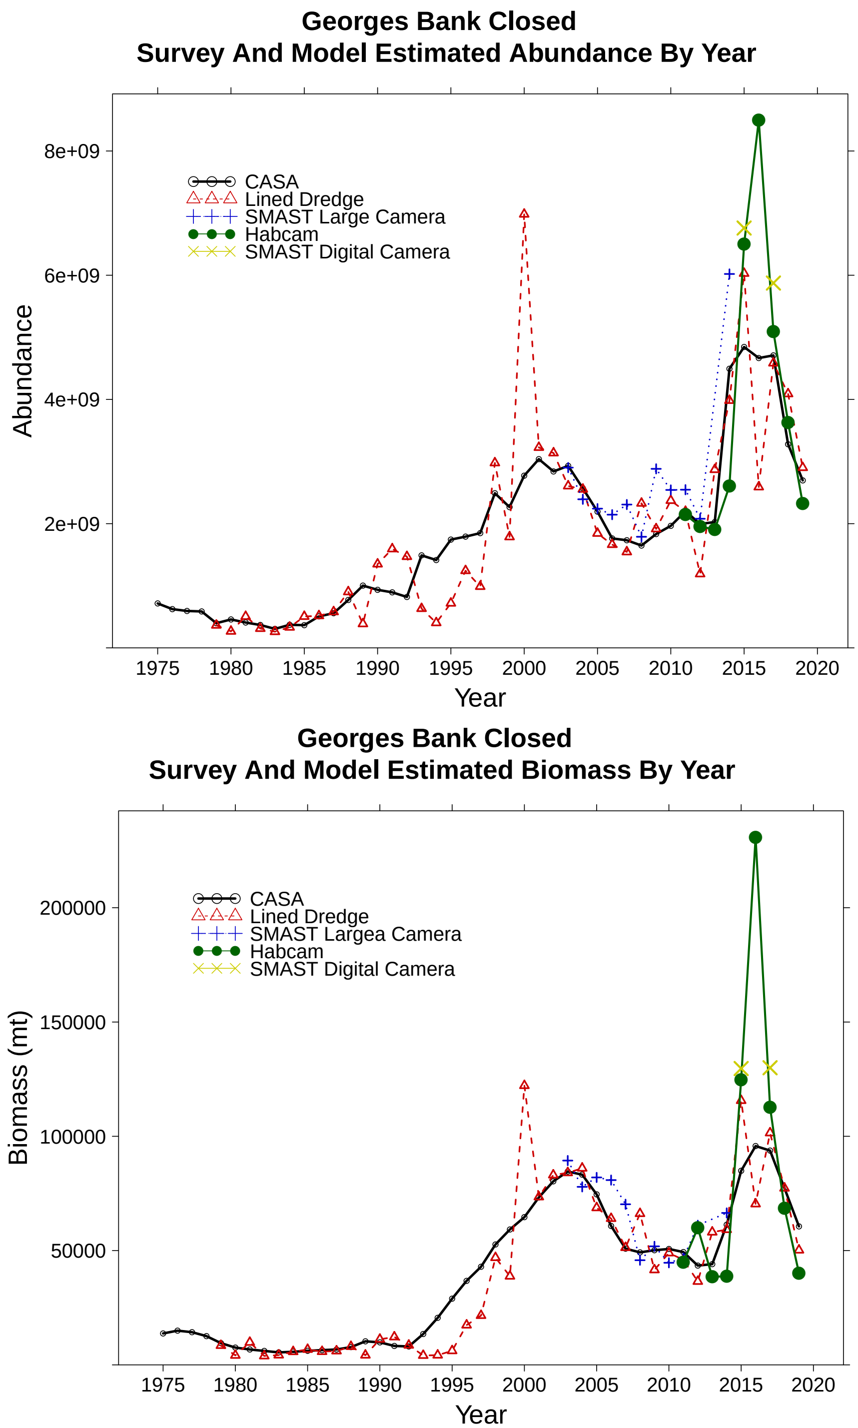

Figure 22: Comparison of CASA model estimated abundance (top) and biomass (bottom) with expanded estimates from the lined dredge (red), SMAST large camera (blue), HabCam (green), and SMAST digital camera (light green) for Georges Bank closed areas.

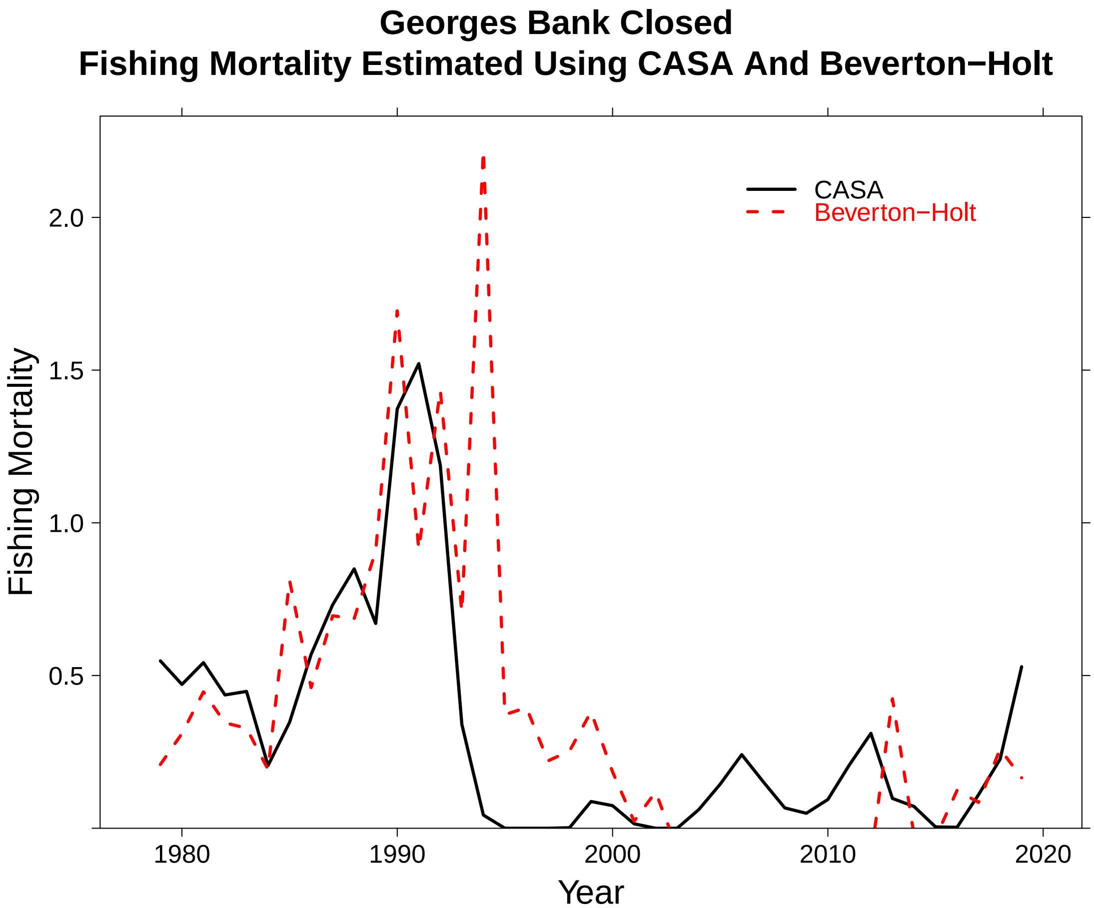

Figure 23: Comparison of fully recruited CASA fishing mortality with those calculated from the Beverton-Holt equilibrium length based estimator for Georges Bank closed areas.

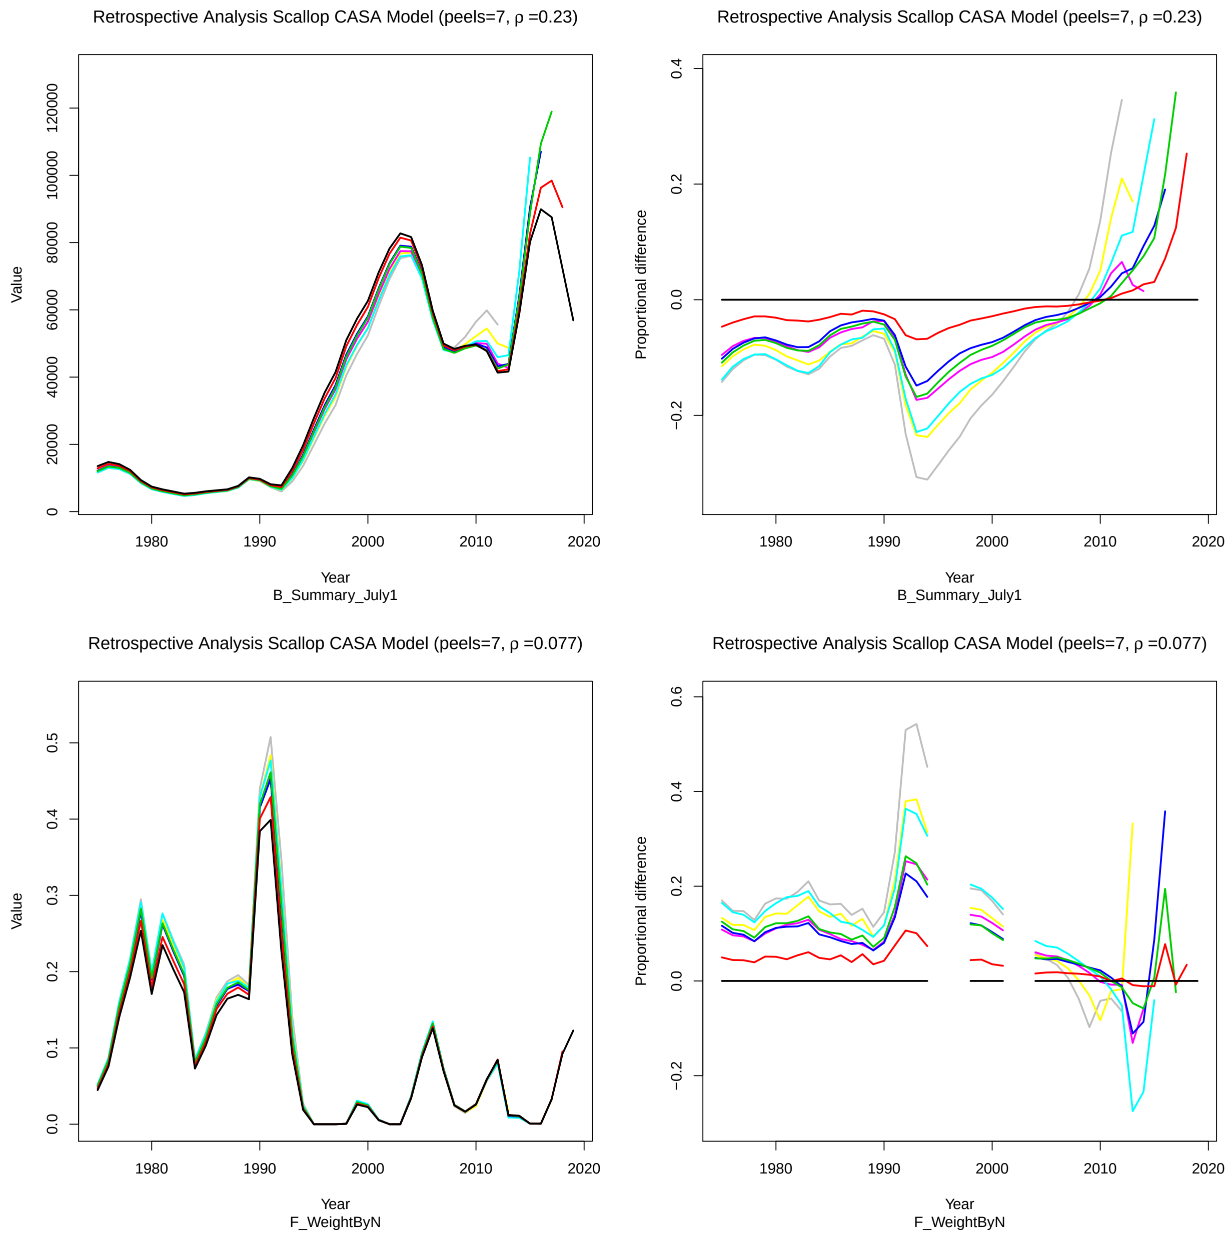

Figure 24: Retrospective plots for biomass and fishing mortality for Georges Bank closed areas. Retrospectives are shown on both absolute and relative scales.

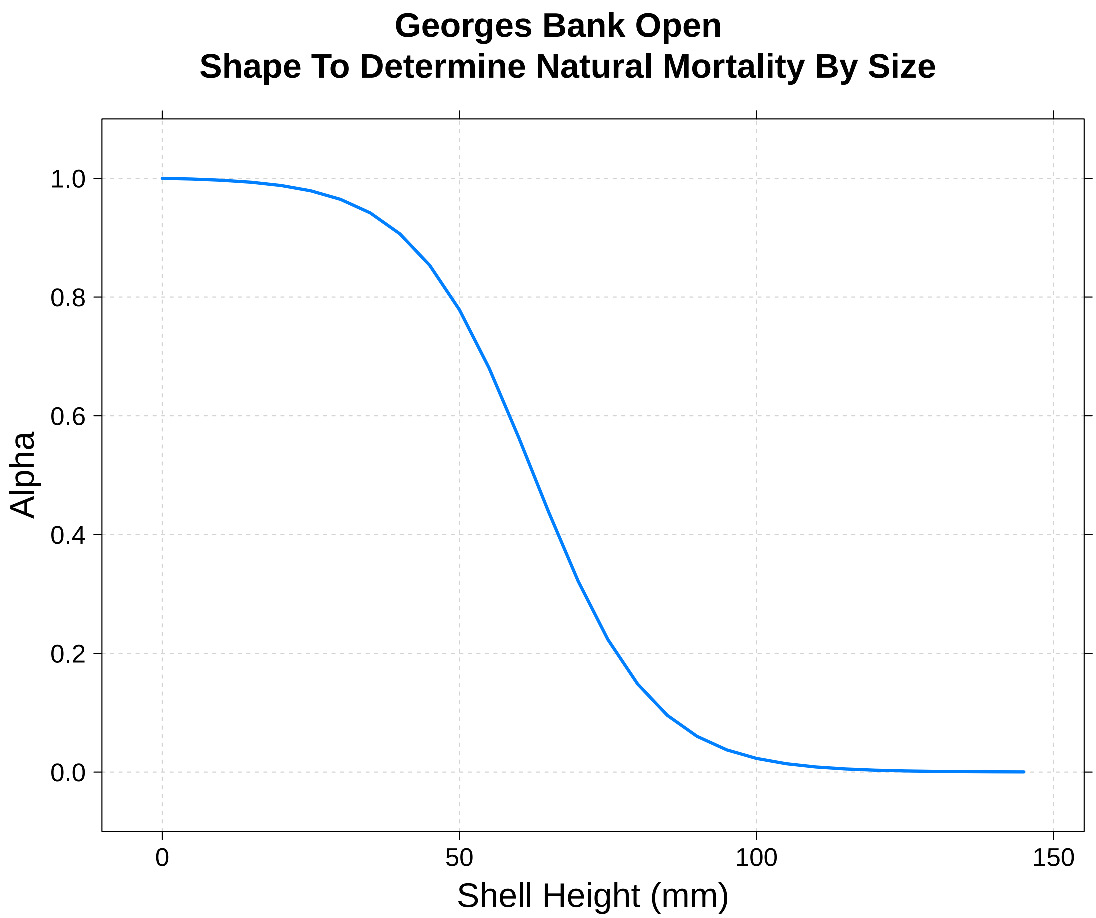

Figure 25: Logistic curve used to partition juvenile and adult natural mortality for Georges Bank open areas.

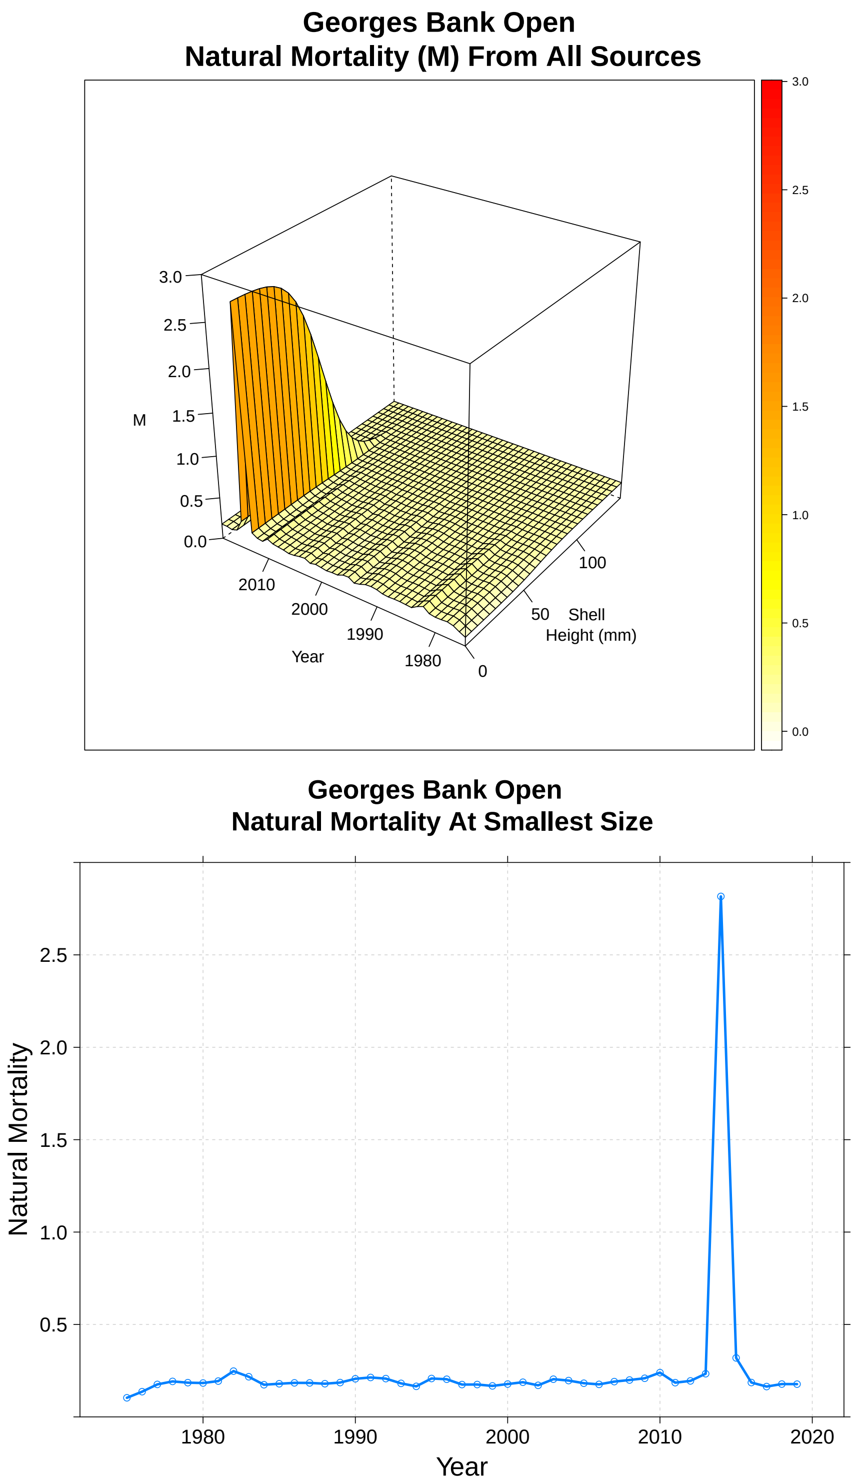

Figure 26: Estimated natural mortality by size (top) and for smallest size group (bottom) from 1975 to 2019 for Georges Bank open areas.

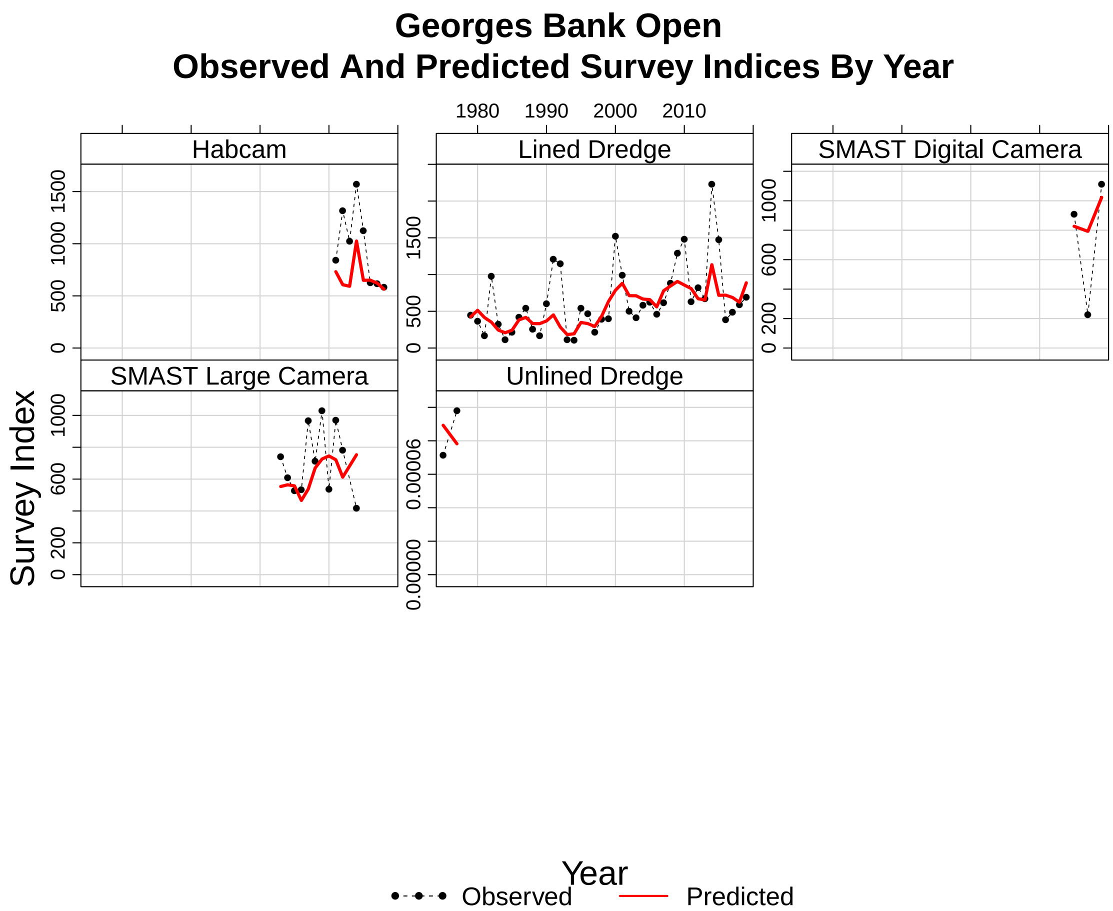

Figure 27: Observed survey trend (solid circles) and corresponding model estimates (lines) for the SMAST digital camera (top left), lined dredge (top middle), Habcam (top right), SMAST large camera (bottom left), and unlined dredge (bottom middle) surveys on Georges Bank open areas.

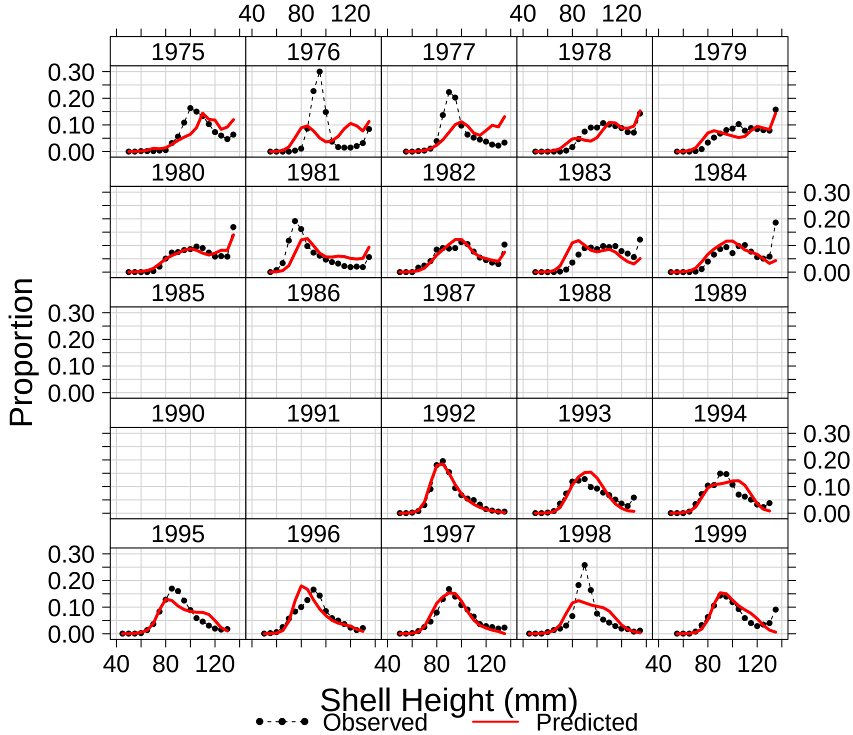

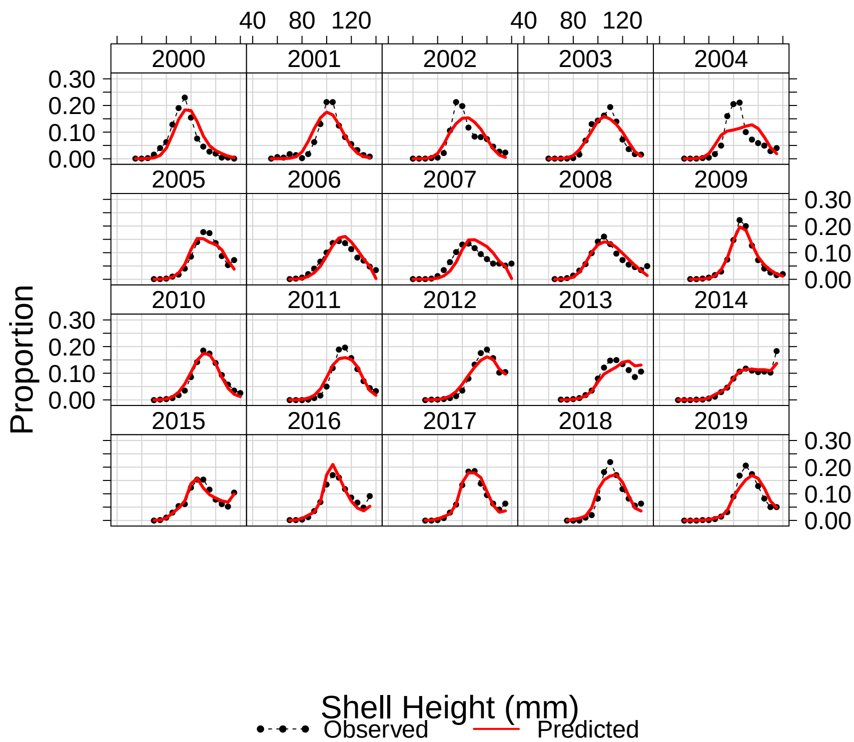

Figure 28: Comparison of observed fishery shell height proportions (solid circles) and model estimated fishery shell height proportions (lines) for Georges Bank open areas.
