#### Abstract

The combined Canada/US Yellowtail Flounder catch in 2016 was 44 mt , with neither country filling its portion of the quota. This is the lowest catch in the time series which began in 1935. Despite the low catch, all three bottom trawl surveys declined.

The empirical approach recommended at the 2014 Diagnostic Benchmark was applied in this year's assessment update. The three recent bottom trawl surveys were scaled to absolute biomass estimates, averaged, and an exploitation rate of $2 \%$ to $16 \%$ was applied to generate catch advice of 20 mt to 158 mt . An intersessional TRAC conference call examined results from twin-trawl and ground gear studies and concluded that survey catchability should be 0.31 instead of 0.37 and that wing spread instead of door spread should be used when calculating the area of a survey tow. These two changes caused the average survey biomass to increase approximately three fold for the entire time series. The TRAC will discuss the appropriate exploitation rate to apply to the new time series.

## RÉSUMÉ

## INTRODUCTION

The Georges Bank Yellowtail Flounder (Limanda ferruginea) stock is a transboundary resource in Canadian and US jurisdictions. This paper updates the last stock assessment of Yellowtail Flounder on Georges Bank, completed by Canada and the US (Legault and Busawon 2016), taking into account advice from the 2014 Diagnostic and Empirical Approach Benchmark (hereafter 2014 Diagnostic Benchmark; O’Brien and Clark 2014). During the June 2014 Transboundary Resources Assessment Committee (TRAC) assessment, it was decided to no longer use the virtual population analysis model which had previously provided stock condition and catch advice. This assessment follows that decision and does not provide any stock assessment model results. The 2014 Diagnostic Benchmark recommended an empirical approach to providing catch advice based on the three bottom trawl surveys and an assumed exploitation rate.

Last year, the empirical approach for catch advice was used with an exploitation rate of $2 \%$ to $16 \%$ resulting in a total quota of 31 mt to 245 mt . The Transboundary Management Guidance Committee (TMGC) selected the combined US-Canada catch quota for 2017 to be 300 mt .

## MANAGEMENT

The management unit currently recognized by Canada and the US for the transboundary Georges Bank stock includes the entire bank east of the Great South Channel to the Northeast Peak, encompassing Canadian fisheries statistical areas 5Zj, 5Zm, 5Zn and 5Zh (Figure 1a) and US statistical reporting areas 522, 525, 551, 552, 561 and 562 (Figure 1b).

## THE FISHERIES

Exploitation of the Georges Bank Yellowtail Flounder stock began in the mid-1930s by the US trawler fleet. Catch (including discards) increased from 400 mt in 1935 to the highest annual catches during 1963-1976 (average: 17,500 mt) and included modest catches by distant water fleets (Table 1 and Figure 2a). A directed Canadian fishery began on eastern Georges Bank in 1993, pursued mainly by small otter trawlers ( $<20 \mathrm{~m}$ ). In 2001, the decision was made to manage the stock as a transboundary resource in Canadian and US jurisdictions (TMGC 2002). Since 2004, decreasing quotas, and catches below these quotas, have resulted in a declining trend in catches through 2016 (Figure 2b). Catch in 2016 was 44 mt , the lowest value over the time series (1935-2016).

## UNITED STATES

The principle fishing gear used in the US fishery to catch Yellowtail Flounder is the otter trawl, accounting for more than $95 \%$ of the total US landings in recent years, although scallop dredges have accounted for some historical landings. Recreational fishing for Yellowtail Flounder is negligible.

Landings of Yellowtail Flounder from Georges Bank by the US fishery during 1994-2016 were derived from the trip-based allocation algorithm (GARM 2007; Legault et al. 2008; Palmer 2008; Wigley et al. 2007a). US landings have been limited by quotas in recent years. Total US Yellowtail Flounder landings (excluding discards) for the 2016 fishery were 26 mt (Table 1 and Figure 2a-b).

US discarded catch for years 1994-2016 was estimated using the Standardized Bycatch Reporting Methodology (SBRM) as recommended in the GARM III Data meeting (GARM 2007, Wigley et al. 2007b). Observed ratios of discards of Yellowtail Flounder to kept of all species for
large mesh otter trawl, small mesh otter trawl, and scallop dredge were applied to the total landings by these gears and by half-year (Table 2). Large and small mesh otter trawl gears were separated at 5.5 inch $(14 \mathrm{~cm})$ cod-end mesh size. Total discards of Yellowtail Flounder in the US were 7 mt in 2016.

The total US catch of Georges Bank Yellowtail Flounder in 2016, including discards, was 33 mt .
The US Georges Bank Yellowtail Flounder quota for fishing year 2016 (1 May 2016 to 30 April 2017 for groundfish and 1 March 2016 to 28 February 2017 for scallops) was set at 269 mt . Monitoring of the US catches relative to the quota was based on Vessel Monitoring Systems (VMS) and a call-in system for both landings and discards. Reporting on the Regional Office webpage (NOAA Fisheries Northeast Multispecies (Groundfish) Monitoring Reports) indicates the US groundfish fishery caught $9.5 \%$ of its 250.8 mt sub-quota and the scallop fleet caught $5.0 \%$ of its 42 mt sub-quota for their 2016 fishing years. The sum of groundfish and scallop subquotas reported above exceeds the US quota because a portion of the scallop quota was reallocated to the groundfish fishery during the year and is counted in both sub-quotas above.

Uncertainty in the US catch of Georges Bank Yellowtail Flounder remains due to allegations of catch misreporting currently under litigation.

## CANADA

Canadian fishermen initiated a directed fishery for Yellowtail Flounder on Georges Bank in 1993, but landings have been less than 100 mt every year since 2004, with less than 1 mt in 2013, 2014, and 2016 and 3 mt in 2015. Since 2004, with the exception of 2011 and 2012, there has been no directed Canadian Yellowtail Flounder fishery (the fishery is not permitted to target Yellowtail Flounder, nor use gear appropriate for targeting this species); the Canadian quota has been reserved to cover bycatch in the commercial groundfish and scallop fisheries. From 2004-2011, and during 2013-2016, most of the reported Yellowtail Flounder landings were from trips directed for Haddock.

The Canadian offshore scallop fishery is the only source of Canadian Yellowtail Flounder discards on Georges Bank. Discards are estimated from at-sea observer deployments using the methodology documented in Van Eeckhaute et al. (2005). Since August 2004, there has been routine observer coverage on vessels in the Canadian scallop fishery on Georges Bank (Table 3). Discards for the years 2004-2016 were obtained by estimating a monthly prorated discard rate (kg/(hr*meters)), using a 3-month moving-average calculation to account for the seasonal pattern in bycatch rate, applied to a monthly standardized effort (Tables 4-5) (Sameoto et al. 2013; Van Eeckhaute et al. 2011). The result of these calculations for 2016 is a discard estimate of 10 mt , the lowest in the time series (Table 1).
For 2016, the total Canadian catch, including discards, was 10 mt , which is $12 \%$ of the 2016 quota of 85 mt .

## LENGTH AND AGE COMPOSITION

Despite low landings, the level of US port sampling continued to be proportionally strong in 2016, with 497 length measurements available, resulting in 1,894 lengths per 100 mt of landings (Table 6). This level of sampling has generally resulted in high precision (i.e. low coefficients of variation) for the US landings at age from 1994-2016 (Table 7). The port samples also provided 271 age measurements for use in age-length keys. The Northeast Fisheries Observer Program provided an additional 67 length measurements of discarded fish, which were combined with the port samples to characterize the size composition of the US catch.

In 2016, no samples were collected from the 1 mt of Canadian landings (Table 6). The Canadian landings at age were assumed to follow the same proportions at age as the US landings and to have the same weights at age as the US landings.

The US discard length frequencies were generated from observer data, expanded to the total weight of discards by gear type and half year. The low amounts of discards in 2016 meant few observations could be made of the length distributions of these catches.

The size composition of Yellowtail Flounder discards in the Canadian offshore scallop fishery was estimated by half year using length measurements obtained from 23 observed trips in 2016. These were prorated to the total estimated bycatch at size using the corresponding half year length-weight relationship and the estimated half year bycatch ( mt ) calculated using the methods of Stone and Gavaris (2005).

The low magnitude of both landings and discards by both countries make comparisons of length distributions uninformative.

Percent agreement on scale ages by the US readers continues to be high (>85\% for most studies) with no indication of bias (Results of all QA/QC Exercises for Yellowtail Flounder, Limanda ferruginea).

For the US fishery, sample length frequencies were expanded to total landings at size using the ratio of landings to sample weight (predicted from length-weight relationships by season; Lux 1969), and apportioned to age using pooled-sex age-length keys in half year groups. Landings were converted by market category and half year, while discards were converted by gear and half-year. The age-length keys for the US landings used only age samples from US port samples, while age-length keys for the US discards used age samples from US surveys and port samples.

No scale samples were available for the Canadian fishery in 2016. Therefore, the Canadian discards at length were converted to catch at age using the US age-length keys by half-year.

Since the mid 1990s, ages 2-4 have constituted most of the exploited population, with very low catches of age 1 fish due to the implementation of larger mesh (increased from 5.5 to 6 inches in May 1994) in the cod-end of US commercial trawl gear (Table 8 and Figure 3).

The fishery mean weights at age for Canadian and US landings and discards were derived using the applicable age-length keys, length frequencies, and length-weight relationships. The combined fishery weights at age were calculated from Canadian and US landings and discards, weighted by the respective catch at age (Table 9 and Figure 4). The low catches make the 2016 estimated weights at age more uncertain than previous years.

## ABUNDANCE INDICES

Research bottom trawl surveys are conducted annually on Georges Bank by Fisheries and Oceans Canada (DFO) in February and by the US National Marine Fisheries Service (NMFS) Northeast Fisheries Science Center (NEFSC) in April (denoted spring) and October (denoted fall). Both agencies use a stratified random design, though different strata boundaries are used (Figure 5).
The NMFS spring and fall bottom trawl (strata 13-21) and DFO bottom trawl (strata 5Z1-5Z4) survey catches were used to estimate relative stock biomass and relative abundance at age for Georges Bank Yellowtail Flounder. The NMFS scallop survey did not operate in Canadian waters in 2016 (the sixth year in a row this has occurred) and so cannot be used to estimate abundance of Yellowtail Flounder on all of Georges Bank. Conversion coefficients, which adjust for survey door, vessel, and net changes in NMFS groundfish surveys ( 1.22 for BMV oval doors, 0.85 for the former NOAA ship Delaware II relative to the former NOAA ship Albatross IV, and
1.76 for the Yankee 41 net; Rago et al. 1994; Byrne and Forrester 1991) were applied to the catch of each tow for years 1973-2008.

Beginning in 2009, the NMFS bottom trawl surveys were conducted with a new vessel, the NOAA ship Henry B. Bigelow, which uses a different net and protocols from the previous survey vessel. Conversion coefficients by length have been estimated for Yellowtail Flounder (Brooks et al. 2010) and were applied in this assessment when examining the entire survey time series, but not in the empirical approach.

The DFO survey in 2017 was delayed due to mechanical issues. There is no indication that the survey delay impacted the survey abundance estimates.

Trends in Yellowtail Flounder biomass indices from the three surveys track each other quite well over the past two decades, with the exception of the DFO survey in 2008 and 2009, which were influenced by single large tows (Tables 10-12; Figures 6-7). The 2017 DFO biomass is the lowest in the 31 year time series. The 2017 NMFS spring biomass is the lowest in the 50 year time series. The 2016 NMFS fall biomass is the third lowest in the 54 year time series. These survey biomass levels are below those observed in the mid-1990s when the stock was declared collapsed (Stone et al. 2004).

The spatial distribution of catches (weight/tow) for the most recent year compared with the previous ten year average for the three groundfish surveys show that Yellowtail Flounder distribution on Georges Bank in the most recent year has been consistent relative to the previous ten years (Figure 8a-b). Since 1996, most of the DFO survey biomass and abundance of Yellowtail Flounder has occurred in strata 5Z2 and 5Z4 (Figure 9a). However, in 2008 and 2009 almost the entire Canadian survey catch occurred in just one or two tows in stratum 5Z1, making interpretation of trends over time difficult. The NMFS bottom trawl surveys have been dominated by stratum 16 since the mid 1990s (Figure 9b-c).

Age-structured indices of abundance for NMFS spring and fall surveys were derived using survey specific age-length keys (Tables 10-12; Figure 10a-c). There is some indication of cohort tracking in all three of the bottom trawl surveys (Figure 11a-c). Even though each index is noisy, the age specific trends track relatively well among the three surveys (Figure 12).

The condition factor (Fulton's K) of Yellowtail Flounder has declined during the available time series in all three surveys (Figure 13a-b).
Relative fishing mortality (fishery catch biomass/survey biomass, scaled to the mean for 19872007) was quite variable but followed a similar trend for all three surveys, with a sharp decline to low levels since 1995 (Figure 14). In contrast, time series of total mortality (Z) estimated from the three bottom trawl surveys using the Sinclair (2001) method indicate high values since 1995 (Figure 15).

## EMPIRICAL APPROACH

The 2014 Diagnostic Benchmark recommended an empirical approach be considered for catch advice. The three bottom trawl surveys are used to create a model-free estimate of population abundance. For the two NMFS surveys, the Henry B. Bigelow data are used directly (i.e. uncalibrated values) in these calculations to avoid the complexities that arise due to calibration with the Albatross IV (Table 13). The stratified mean catch per tow in weight is expanded to total biomass based on the ratio of the total area surveyed to the area of a single trawl using door width to calculate the area of a tow (Table 14). Note the values in Table 14 differ slightly from those used previously. The current values are based on Brooks and Politis (2014), except for the DFO Western 2A door width, which is set equal to 37.4 m based on personal communications with DFO scientists. This minimum swept area biomass is divided by the survey catchability of 0.37 to create an estimate of the biomass. A literature estimate of the
catchability of the gear, meaning the number of Yellowtail Flounder in the path of the tow which were caught, is used to expand the minimum swept area amount to total abundance. This literature value for catchability was derived in working paper 13 of the 2014 Diagnostic Benchmark as the mean of the value 0.22 in Harden Jones et al. (1977) and four values of 0.33 , $0.42,0.43$, and 0.45 in Somerton et al. (2007). The Harden Jones et al. (1977) study was conducted with English plaice in the North Sea using a Granton otter trawl. The Somerton et al. (2007) study was conducted with four flatfish species (arrowtooth flounder, flathead sole, rex sole, and Dover sole) in the Gulf of Alaska using a Poly nor'eastern survey trawl. The survey biomass estimates from DFO and the NMFS spring survey in year $t$ and the NMFS fall survey in year t-1 are averaged to form the estimate of population biomass in year t . Multiplying the average biomass by an exploitation rate of 0.02 to 0.16 results in the range of catch advice for year t+1 (Table 15). The catch advice for 2018 using door width and survey catchability of 0.37 is 19 mt to 155 mt . The resultant exploitation rate associated with the quota or catch can be computed by dividing each by the average survey biomass from that year (Table 16).

A TRAC intersessional conference call on June 26, 2017 reviewed three working papers that addressed survey catchability and tow area. Two of the working papers estimated survey catchability based on a twin trawl experiment conducted in 2015 and 2016 (Miller et al. 2017, Richardson et al. 2017). One of the twin trawl nets used the NMFS standard rockhopper sweep while the other net used chain gear to prevent flounders from escaping under the sweep. After discussing the merits of both approaches, a practical consensus was achieved that set survey catchability to 0.31 based on the statistically best fitting models that incorporated length effects and diel effects. The other working paper described a bridle study experiment that examined the effect of different lengths of ground gear connecting the net to the doors to determine if herding of flatfish was occurring (Politis and Miller 2017). The results of this study were not definitive, but indicated that herding was probably not a strong feature of the NMFS bottom trawl. This led to the consensus decision to use wing width instead of door width when calculating the area of a survey tow. Both decisions were applied to all three surveys. The average biomass under these two new conditions is approximately three times the average biomass computed from the 2014 Diagnostic Benchmark settings (compare Tables 15 and 17). Applying an exploitation rate of 0.02 to 0.16 results in a range of catch advice for 2018 of 62 mt to 495 mt . It is not clear whether this range of exploitation rates is appropriate under the new conditions though. This is seen by comparing the resultant exploitation rates associated with either the quota or catch (Tables 16 and 18). The 2014 Diagnostic Benchmark formulation has an exploitation rate associated with the quota that averaged $20 \%$ ranging from $10 \%$ to $37 \%$ and an exploitation rate associated with the catch that averaged $7 \%$ ranging from $3 \%$ to $16 \%$. The higher biomass associated with the new conditions of door width and survey catchability $=0.31$ causes these historical exploitation rates to decrease with the quota averaging $6 \%$ (range 3\% to 12\%) and the catch averaging 2\% (range $1 \%$ to $5 \%$ ). Given the decline in all three surveys in this past year, despite the catch being well below the quota, it is not clear that increasing the exploitation rate up to $16 \%$ is the appropriate management advice.

The empirical approach as described above consists of point estimates for all parameters. There are a number of uncertain elements that can be incorporated in a Monte Carlo evaluation to examine the uncertainty in the catch advice. The surveys have coefficients of variation that are reported each year, the experiment that estimated the new survey catchability of 0.31 had uncertainty estimates reported, there may be untrawlable regions on Georges Bank where Yellowtail Flounder are not found (meaning the survey area is less than the nominal value used in the calculations), and there may be some herding of Yellowtail Flounder. Each of these uncertainties can be examined one at a time (Figure 16) and all of them together (Figure 17). Examining the factors one at a time shows the low uncertainty of survey area (uniform 0.95 1.00) and tow area (uniform $1.0-1.2,1.2$ means $20 \%$ increase in tow area due to herding), relative to the higher uncertainty of the chain to rockhopper survey catchability estimate
(lognormal with $\mathrm{CV}=0.65$ ), and the highest uncertainty associated with the survey catch per tow. Combining the results indicates that despite the uncertainty, there is a strong indication that catch advice should have decreased during this time period because there is little overlap between the distributions early in the time series and those late in the time series.

## MANAGEMENT CONSIDERATIONS

During the 2014 Diagnostic Benchmark, considerations were provided as reasons to decrease or to maintain or increase the quota. The assessment findings this year support reasons to both decrease the quota and to maintain or increase the quota for 2018. Last year's catch was less than $15 \%$ of the quota, the relative F continues to be low, and bycatch avoidance programs continue, which support maintaining or increasing the quota. All three of the surveys declined last year (two of the surveys to the lowest value in the time series, the other to the third lowest in its time series), recent recruitment continues to be below average, and fish condition (i.e., Fulton's K) continues to be low relative to the available time series, which support decreasing the quota.

During the 2016 TRAC meeting, a reviewer asked whether times series of recruits per spawning stock biomass had been examined using only data from the surveys. The request was premised on the concern that changes in recruits per spawning stock biomass could be masking important trends in recruitment. For example, if recruits per spawning stock biomass increased over time, it could result in recruitment staying relatively high while spawning stock biomass declined, which would be of biological concern because this pattern could not continue indefinitely. Alternatively, if recruits per spawning stock biomass declined at low spawning stock biomass, this could be an indication of depensation in the stock-recruitment relationship, which would be concerning for the ability of the stock to rebuild even under no fishing. For each of the three surveys, both age 1 and age 2 were used for recruitment and appropriately lagged relative to total biomass from that survey to create a proxy for the recruits per spawning stock biomass. Age 2 was examined because the age 1 survey values contained many zeros. The time series of recruits per survey biomass were variable without strong trend but have been low in recent years in all cases (Figure 18). There is an indication of depensation in recent years because the recent recruits per biomass are low relative to earlier recruits per biomass at similar biomasses (Figure 19). This could have strong implications for the (in)ability of the stock to rebuild even under no fishing.

FIGURES

Figure 1a. Location of statistical unit areas for Canadian fisheries in NAFO Subdivision 5Ze.Catches of Yellowtail Flounder in areas 5Zhjmn are used in this assessment.

Figure 1b. Statistical areas used for monitoring northeast US fisheries. Catches from areas 522, 525, 551, 552, 561 and 562 are included in the Georges Bank Yellowtail Flounder assessment. Shaded areas have been closed to fishing year-round since 1994, with exceptions.

Figure 2a. Catch (landings plus discards) of Georges Bank Yellowtail Flounder by nation and year.

Figure 2b. Recent catches by country and quotas. Note the US quota is not applied for the calendar year and that in 2010 the TMGC could not agree on a quota, so the 2010 value is the sum of the implemented quotas by each country.

Figure 3. Catch at age (left panel) and catch proportions at age (right panel) for Georges Bank Yellowtail Flounder (Canadian and US fisheries combined). The area of the bubble is proportional to the magnitude of the catch or proportion. Diagonal red lines denote the 1975, 1985, 1995, and 2005 year-classes.

Figure 4. Trends in mean weight at age from the Georges Bank Yellowtail Flounder fishery (Canada and US combined, including discards). Dashed lines denote average of time series.

Figure 5. DFO (top) and NMFS (bottom) strata used to derive research survey abundance indices for Georges Bank groundfish surveys. Note NMFS stratum 22 is not used in assessment.

Figure 6. Three survey biomass indices (DFO, NMFS spring, and NMFS fall) for Yellowtail Flounder on Georges Bank rescaled to their respective means for years 1987-2007.

Figure 7. Survey biomass for Yellowtail Flounder on Georges Bank in units of kg/tow with $90 \%$ confidence intervals from +/-1.645*stdev (DFO) or bootstrapping (NMFS spring and NMFS fall).

Figure 8a. Catch of Yellowtail Flounder in weight (kg) per tow for DFO survey: recent ten year average (top panel) and most recent year (bottom panel).

Figure 8b. Catch of Yellowtail Flounder in weight (kg) per tow for NMFS spring (top) and NMFS fall (bottom) surveys. Left panels show previous 10 year averages, right panels most recent data. Note the 2009-2017 survey values were adjusted from Henry B. Bigelow to Albatross IV equivalents by dividing Henry B. Bigelow catch in weight by 2.244 (spring) or 2.402 (fall).

Figure 9a. DFO survey estimates of total biomass (top panel) and total number (bottom panel) by stratum area for Yellowtail Flounder on Georges Bank.

Figure 9b. NMFS spring survey estimates of total biomass (top panel) and proportion (bottom panel) by stratum for Yellowtail Flounder on Georges Bank.

Figure 9c. NMFS fall survey estimates of total biomass (top panel) and proportion (bottom panel) by stratum for Yellowtail Flounder on Georges Bank.

Figure 10a. Age specific indices of abundance for the DFO survey including the large tows in 2008 and 2009 (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

Figure 10b. Age specific indices of abundance for the NMFS spring survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

Figure 10c. Age specific indices of abundance for the NMFS fall survey (the area of the bubble is proportional to the magnitude). Diagonal red lines denote the 1965, 1975, 1985, 1995, and 2005 year-classes.

Figure 11b. NMFS spring survey catch at age by cohort on log scale. Red lines denote linear regression and blue lines denote $95 \%$ prediction interval for the linear regression. Correlation values are shown in lower right triangle.

Figure 11c. NMFS fall survey catch at age by cohort on log scale. Red lines denote linear regression and blue lines denote $95 \%$ prediction interval for the linear regression. Correlation values are shown in lower right triangle.

Figure 12. Standardized catch/tow in numbers at age for the three surveys. The standardization was the division of each index value by the mean of the index during 1987 through 2007.

Figure 13a. Condition factor (Fulton's K) of Georges Bank Yellowtail Flounder from the NMFS fall and spring surveys.

Figure 13b. Condition factor (Fulton's K) for male and female Yellowtail Flounder in the DFO survey.

Figure 14. Trends in relative fishing mortality (catch biomass/survey biomass), or relative F, standardized to the mean for 1987-2007.

Figure 15. Total mortality ( $Z$ ) estimated using method of Sinclair (2001) with four year moving window catch curve analysis using cohorts of ages 3-8. The midpoint of the four year moving window is plotted as Year (e.g., years 2014-2017 are plotted as 2015.5). The filled circles denote the estimated values and the shaded region the 95\% confidence intervals. The total mortality estimates from the DFO survey are in red, from the NMFS spring survey are in blue, and from the NMFS fall survey are in black.

Figure 16. Distribution of catch advice over time from 1000 Monte Carlo evalations of four types of uncertainty. The dots show the point estimates.

Figure 17. Distribution of catch advice from 1000 Monte Carlo evaluations with all four sources of uncertainty. The dots show the point estimates.

Figure 18. Recruits (at age 1 in top three panels, at age 2 in bottom three panels) per total biomass (a proxy for recruits per spawning stock biomass) over time from the three bottom trawl surveys. Recruits per biomass values of zero are not shown.

Figure 19. Recruits (at age 1 in top three panels, at age 2 in bottom three panels) per total biomass (a proxy for recruits per spawning stock biomass) in relation to the survey biomass. Blue filled circles denote years since 2011 (not all plots show each year due to zeros treated as missing values).

## APPENDIX

The table below was kindly initiated by Tom Nies (NEFMC). It summarizes the performance of the management system. It reports the TRAC advice, TMGC quota decision, actual catch, and realized stock conditions for Georges Bank Yellowtail Flounder.
(1) All catches are calendar year catches
(2) Values in italics are assessment results in year immediately following the catch year; values in normal font are results from this assessment

| TRAC | Catch | TRAC Analysis/Recommendation |  | TMGC Decision |  | Actual | Actual Result ${ }^{(2)}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
